## EFFECT OF BEATING ON THE BRIGHTNESS OF UNBLEACHED SULFITE PULP

(Using Distilled and Tap Water)

### OBJECTIVE

The use of tap water in pulp evaluation studies introduces the possibility of another significant variable. Recent publications, of English and Australian origin, have established the influence of certain tap water ions on the physical characteristics of refined pulp. This work has not, however, been comprehensive. The objective of this work is twofold. First, to establish a quantitative relationship between degree of beating and brightness (General Electric reflectance) of a typical unbleached sulfite pulp. Second, to determine whether the use of Appleton city tap water in the beating process produces a deleterious effect on the pulp brightness. The pulp used was ~~Kapuskasing~~ unbleached sulfite.

### PROCEDURE

A sample of the pulp was beater evaluated (3-29-48) following Institute Method 403 (No. 3 Beater - 5,500 g. bedplate loading). In this method tap water is used throughout the beating and subsequent sheet making operations. Regular British handsheets were prepared and dried according to Institute Method 411. Beater intervals were 0, 5, 10, 25, and 40 minutes.

p 12

A second sample of the pulp was evaluated and formed into handsheets employing the above procedures with the following deviations. Distilled water was used in the beating and handsheet preparation. Interval samples were 0, 5, 10, 25, 40, 55, and 70 minutes. When preparing handsheets with distilled water, tap water was used under the wire.

The handsheets from both evaluations were conditioned 48 hours at 73° F, 50% R.H. before the General Electric reflectance was determined. Reflectance was determined for both the rough (felt) and smooth (wire) side. Wire side, as used here, is a misnomer because during drying the wire side remains in contact with a metal disc which produces a glossy surface on that side.

#### RESULTS AND CONCLUSIONS

The data have been listed in tabular form. See Table I. Examination shows that significant differences in brightness were not obtained when the unbleached sulfite pulp was beaten and formed into handsheets using distilled water throughout as compared to the normal treatment using tap water. Critical examination of the data indicate a general trend of slightly higher brightness for the tap water treatment, but this is probably due to normal variations of the processing and testing procedures.

Figure 1 is a graphic representation obtained for the quantitative relationship of degree of beating and General Electric brightness. Here the distilled water run was chosen because of the more extensive coverage of the freeness range. In this instance, using distilled water, the reduction in brightness produced by beating is a result of changes in

scattering power of the handsheet optical surface. This light scattering power is closely associated with the more general term "texture."

The results of this work should not be construed in a general manner. It should be realized that identical results, speaking qualitatively, may not be obtained with a "high white" pulp, and that the effect of tap water may be subject to seasonal variations in water supply.

## EFFECT OF TAP WATER ON THE TENSILE STRENGTH OF UNBLEACHED SULPHITE PULP (Distilled and Tap Water Comparison)

The use of tap water in pulp evaluation studies may effect pulp quality and paper physical characteristics. These effects, however, are specific with water supply. A study of the Appleton city water; its effect on brightness, was made.

Refer to May 18, 1948, report of Project 1102-3, the Effect of Beating on the Brightness of Unbleached Sulphite Pulp. This report covers an extension of that work wherein tensile strength determinations were made on samples taken from the brightness study.

### Procedure

A sample of pulp was beater evaluated (3-29-48) following Institute Method 403 (No. 3 beater - 5,500 gm. bedplate loading). In this method tap water is used throughout the beating and subsequent sheet-making operations. Regular British handsheets were prepared and dried according to Institute Method 411. Beater intervals were 0, 5, 10, 25, and 40 minutes.

A second sample of the pulp was evaluated and formed into handsheets as described in the above procedure with the exception that distilled water was used in place of tap water and the intervals were extended to include 0, 5, 10, 25, 40, 55, and 70 minutes. When preparing the handsheets with distilled water, tap water was used under the wire.

The handsheets from both evaluations were conditioned for 48 hours at 73° F. 50% R. H. before General Electric reflectance was determined. These results have been reported. Data on Schopper tensile strength results were obtained from the specimens (1-1/2 by 2 inches) used for the brightness determinations in May 18, 1948, report. The length of the tensile strip was one inch.

#### Results and Conclusions

The data have been listed in Table I. Examination shows that significant differences in tensile strength were not obtained when the unbleached sulphite pulp was beaten and formed into handsheets using distilled water throughout as compared to using the normal treatment of tap water. It should be noted, however, that the tap water run was not carried to the lower freeness range of the distilled water evaluation.

Figure I is a graphic comparison of tensile strength versus freeness of both the tap water and distilled water evaluations.

These results should not be given general interpretation since identical results, speaking qualitatively, may not be obtained with all of the various type pulps, and tap water effects may be subject to seasonal variations in water supply.

Notes: The handshets were conditioned and tested at 50% R.H., 73° F.  
 All the data in this report were obtained from the specimens  
 (1-1/2 by 2 inches) used for the brightness determinations.  
 The length of the tensile strip was one inch.  
 Weight on bedplate = 5500 grams.

## CORRELATION OF PHYSICAL PROPERTIES OF VARIOUS PULPS

This work was done in an attempt to establish a correlation between strength data and caliper and apparent density on British hand-sheets. Most of the data was taken from work reported on earlier projects.

The projects investigated were as follows:

| Project No. | Co-operator                       |
|-------------|-----------------------------------|
| 1126        | Crown Zellerbach Corporation      |
| 1274-C      | Crown Zellerbach Corporation      |
| 1348        | Howard Paper Mills, Inc.          |
| 1425        | Kalamazoo Vegetable Parchment Co. |
| 1457        | Fibreboard Products Inc.          |
| 1481        | Nekoosa-Edwards Paper Company     |

The majority of the data was taken from standard Valley beater evaluations of the various pulps. If the procedure was modified or if a different refiner was used, it is mentioned in this report. Most of the data was taken from Code Office reports. It is not tabulated, but the file numbers are shown to facilitate future reference. Any data not obtained from Code Office reports are tabulated in this report.

The graphs drawn for this study were merely rough sketches, and no copies were made. The original graphs are attached to the file copy of this report.

The data taken from Project 1126 were physical properties of Douglas fir, hemlock, and cedar kraft pulps. The Institute file numbers for these data are 121669, 121673, and 121696.

Figure 1 is a plot of bursting strength, tensile strength, and tear factor vs. caliper for the hemlock and Douglas fir pulps. From the appearance of these curves, it appears that the strength curves for hemlock pulp may be a continuation of the corresponding curves for Douglas fir pulp with some overlapping occurring at the end of the beating cycle for Douglas fir pulp and at the start of the beating cycle for hemlock pulp.

Figure 2 shows three plots of tensile strength vs. caliper. The bottom curve is the tensile strength in lb./in. vs. caliper as plotted in Figure 1. The next curve is the same except that a basis weight correction has been applied to the tensile strength values. These values were obtained by dividing the tensile strength in lb./in. by the basis weight in lb. and multiplying by 100. The top curve is the same except that a caliper correction has been applied to the tensile strength values. The original tensile strength was merely divided by the caliper.

Neither of the top two curves shows an improvement over the bottom curve as far as showing a continuous curve for the two pulps is concerned.

Figure 3 shows the same values of tensile strength plotted against apparent density. These curves show an improvement over those plotted against caliper. In the bottom curve the cedar pulp is also included, and it seems to fall fairly close to the same line.

Figure 4 is included to show the variation between the tensile strength of Douglas fir and hemlock pulps as indicated by a normal beating curve.

Figure 5 shows the bursting and tearing strength for the three pulps plotted against apparent density. These two properties for the hemlock and Douglas fir pulps do not seem to come any closer to being on a common curve than they did when plotted against caliper in Figure 1. It is noticed that the curves for the cedar pulp lie between those for the hemlock and Douglas fir pulps.

The only strength data obtained on hemlock and Douglas fir pulps in Project 1274-C were tensile strength. The file numbers for these data are 131351 to 131358 for the Douglas fir pulp and 131465 to 131472 for the hemlock pulp. The basis weight of the sheets made for this project was approximately one-half of the normal basis weight for British handsheets.

The tensile strength is plotted against caliper in Figure 6 and against apparent density in Figure 7. Both curves indicate that

the tensile strengths of the two pulps fall on a common curve with Figure 7 showing the least variation of points from this curve.

Figure 8 is included to show the variation between the two pulps as indicated by normal beating curves.

The data from Project 1348 were then investigated to see what an analysis of this type would indicate when different refiners were used on the same pulp. The refiners used were the Valley beater, the Abbé pebble mill, the Lampén ball mill, and the Morden stock maker. The file numbers for these data are 131095 for the Valley beater, 131386 for the Lampén ball mill, 131331 for the Morden stock maker, and 133217 to 133222 for the pebble mill. Plotting bursting and tearing strength against caliper in Figure 9 does not show close agreement between any of the four refiners used except for tearing strength of stock refined in the Valley beater and the Morden stock maker. The tear curve for the stock refined in the Lampén mill is also fairly close to these curves.

Figure 10 shows the same properties plotted against apparent density. This method of plotting shows very close agreement between the Valley beater and the Morden stock maker in both bursting and tearing strength. No tensile strength data were obtained in this project.

Project 1425 was an investigation of four different pulps. The file numbers for these data are 134921, 134970, 134922, 134971, 134941, 134962, 134942, and 134963. In Figures 11 to 13, bursting, tearing, and tensile strength are plotted against caliper. No striking

similarity can be seen between any of the four pulps from these curves. In Figure 14, the bursting strength is plotted against apparent density, and again no similarity can be noticed. In Figure 15, the tensile strength is corrected to be lb./in./100 lb. and plotted against apparent density, and no similarity is noticed.

Project 1457 investigated three species of western firs that were cooked to approximately the same permanganate number. Douglas fir, white fir, and red fir were cooked separately, and a blend consisting of 75% red fir and 25% white fir was also pulped. The file numbers for these data are 136008 for the red fir, 136009 for the white fir, 136010 for the Douglas fir, and 136153 for the blend. The bursting and tearing strength for these pulps are plotted against caliper in Figure 16. These curves show fairly close agreement for the red fir, white fir, and the blend in tearing strength and the red fir and the blend in bursting strength. It is interesting to note that the bursting strength of the Douglas fir and the white fir pulps fall on the same straight line except for the last two beating intervals when the maximum bursting strength has been developed.

In Figure 17, the same properties have been plotted against apparent density, and the curves follow the same trends without appreciable difference, except that the curves are not as straight.

In Project 1481, duplicate beater runs were made on the co-operator's pulp. The file numbers for these data are 137514 and 137515.

Figure 18 shows the normal beating curves for these two beater runs. This graph shows that all the data are in close agreement except for tensile strength.

Figure 19 shows the strength data plotted against caliper. The tearing strength agrees very well for the two beater runs, but the bursting strength shows more variation than in the normal beating curves. The tensile strength still shows a wide variation between the two runs.

In Figure 20, tensile strength is given both a basis weight correction and a caliper correction and plotted against caliper, but neither correction brings the two beater runs into close agreement on tensile strength.

In Figure 21, the strength data are plotted against apparent density with about the same results as shown in Figure 19.

The remainder of this study was confined to an analysis of some data obtained by Mr. Neimeyer in conjunction with setting up Project 1274-C. This work was a study of the effect of variable wet pressing of British handsheets. The Code Office report on this data could not be located so it is tabulated in Tables I and II.

| Excessive wet pressing, moisture content about 35%: |      |      |      |      |      |
| Caliper, in. x 10 <sup>3</sup>                      | 4.6  | 4.4  | 4.1  | 4.1  | 3.9  |
| Density, g./cc.                                     | 0.56 | 0.65 | 0.67 | 0.66 | 0.68 |
| Bursting Strength, pt./100 lb.                      | 61   | 134  | 170  | 169  | 173  |
| Tensile Strength, lb./in. <sup>2</sup>              | 12.7 | 23.2 | 28.4 | 30.0 | 30.0 |
| Tensile Strength, lb./in.                           | 2770 | 5280 | 6930 | 7330 | 7690 |

Figure 22 shows a graph of the properties in Table I plotted against moisture content. This graph indicates that all the properties except caliper give a linear relationship with respect to moisture content.

Figure 23 is a graph of the data from Table II plotted against freeness. This graph shows a comparison of the properties at two degrees of wet pressing. It shows that the density, bursting strength, and tensile strength were increased and the caliper decreased by wet pressing to 35% moisture rather than the usual 65% moisture.

Figure 24 is a graph of the strength data vs. caliper, and Figure 25 is a graph of the same data vs. density. No correlation is evident in these graphs.

#### CONCLUSIONS

From this work, the following conclusions can be drawn:

1. It appears that caliper and apparent density are responsible for the differences in the strengths of hemlock and Douglas fir pulp. If the strength data are plotted vs. either caliper or apparent density, it seems that there may be a possibility of the corresponding data for the two pulps giving a common curve with the hemlock having more bursting and tensile strength and less tearing strength because of its higher apparent density. This could be investigated further by wet pressing Douglas fir handsheets to the same caliper and apparent density as hemlock handsheets and

obtaining strength data on these sheets.

2. When strength data for pulp refined in the Valley beater and the Morden stock maker are plotted vs. apparent density, the bursting strength and tearing strength data give common curves for the two refiners.

3. When plotting strength data for red fir, white fir, and Douglas fir pulps vs. caliper and apparent density, the tearing strength of the red and white fir pulps follow the same curve with the red fir having less tearing strength due to its higher apparent density. The bursting strength of the Douglas fir and white fir pulps follow a common curve up to the point where maximum bursting strength is developed. The white fir pulp has a higher apparent density and a higher bursting strength.

4. Wet pressing handsheets to three different moisture contents and plotting the physical properties vs. the moisture content shows that density, bursting strength, and tensile strength have a linear relationship with respect to moisture content while caliper does not.

5. The degree of wet pressing has a decided effect on the physical properties of the pulp. Wet pressing to a lower moisture content increases density, bursting strength, and tensile strength, and decreases caliper.

6. In a number of the curves plotted, it was noticed that there was a linear relationship for bursting, tearing, and tensile

strengths with respect to caliper for nearly all of the pulps in the middle range of the beating cycle. In some cases this linear relationship covered the entire beating range.

THE EFFECT OF TEMPERATURE OF BEATING AND SHEET FORMATION  
ON STRENGTH CHARACTERISTICS OF BEATER EVALUATED PULP

INTRODUCTION

This work was initiated to determine what influence the extreme variations in water temperature offered by winter and summer might have on beater evaluations made in the laboratory. The temperature of beating and of sheet formation are often, for practical reasons, dependent upon water supply temperature.

This report summarizes the results of the evaluations made at 6° and at 27° C.

EXPERIMENTAL

Institute Method 403 was followed in making the beater evaluations using Weyerhaeuser bleached sulfite as a standard pulp. The low temperature beater runs were made at the prevailing temperature of tap water (6° C.) existing at the time of the runs. A temperature of 27° C. was selected as typical of mid-summer water temperatures. To maintain this temperature during beating, a series of strip heaters, controlled through a "Variac", were fastened to the outside wall of the beater. The

temperature of sheet formation was controlled within 1° C. by addition of warm tap water to the sheet mold.

#### DISCUSSION OF RESULTS AND CONCLUSIONS

Complete evaluation data of the four beater runs are compiled in Table I.

In Table II are summarized the averages of data from the duplicate beater runs made at 6° and 27° C. Figures 1 and 2 are plots of the relationships of beating time to apparent density, burst and tear values. There appears to be no significant difference in the rate of beating at the two temperatures as determined by freeness. However, in the lower freeness range, bursting strength was 10 to 15% higher and tearing strength 40 to 50% higher for the pulps evaluated at the higher temperature. The apparent density of the sheets formed at 27° C. was somewhat lower than those formed at 6° C. Tensile strength seems to be unaffected by the temperature difference employed in this work.

## PRELIMINARY EXPERIMENTS WITH ION-EXCHANGE RESINS

### AS A POSSIBLE METHOD OF SULFITE WASTE LIQUOR UTILIZATION

#### INTRODUCTION

Scaling has long been recognized as the principal obstacle to successful evaporation of sulfite waste liquor. During the course of work on this subject, there has been developed in the laboratory a successful method of evaluating the scaling tendency of a liquor as well as accomplishing the primary objective, reduction of scaling by the use of ion-exchange.

#### EXPERIMENTAL EQUIPMENT

##### A. Laboratory Evaporator

The best possible test of scaling is to duplicate the conditions under which sulfite liquor would be evaporated on a commercial basis. To try to achieve this end, an evaporator was constructed of laboratory glassware. A stainless steel tube, (i.d. 0.308") serves as a heat exchanger. The tube is removable so that scale within can be photographed or dissolved for analysis. There are provisions for either the removal of condensate (concentration) or for returning it to the system (reflux). Evaporation is carried out under vacuum. The evaporator is normally operated with approximately 2,200 cc. of 45-50% O.D. solids liquor. It has heat exchange capacity to remove about 1,200 cc. of condensate per hour. (See Figures 1 and 2 for evaporator details).

Figure 1  
Laboratory Evaporator

Figure 2  
Schematic Diagram  
of  
Laboratory Evaporator.

## B. Ion-Exchange Equipment

Four ion-exchange resins were selected as being typical of the types commercially available. In Table I the resins are tabulated and the dimensions are given for the glass columns in which they are contained. Figure 3 is a photograph of the ion exchange equipment.

TABLE I

## EXPERIMENTAL

Calcium sulfate is usually considered to be the compound chiefly responsible for evaporator scaling. It accounts for approximately 2.5% of the overdry solids of a typical sulfite waste liquor. Four methods of calcium sulfate removal by ion exchange have been considered. By use of cation exchangers, calcium may be replaced by

Figure 3

Laboratory Ion Exchange Columns

either (1) the hydrogen ion, (2) some other cation, frequently sodium. The sulfate ion may be replaced through the use of anion exchangers by (1) the hydroxyl or (2) the chloride ion. In each of these instances sparingly soluble calcium sulfate is converted to a soluble compound. The complete operating cycle for the ion exchange columns in brief is:

- (1) regeneration
- (2) washing
- (3) exhaustion with liquor
- (4) displacement of the liquor with water
- (5) backwashing to clean and reclassify the bed

A procedure has been standardized for making scaling test runs in the laboratory evaporator. A temperature of 62° C. and a vapor head pressure of 23" Hg. vacuum have been arbitrarily selected as operating conditions. Steam at 7 p.s.i. gage is supplied to the heat exchanger. Four liters of liquor to be tested are fed continuously to the evaporator over a period of 2.5 hours. During this same period, 2.8 liters of evaporator condensate are collected in a receiver. When all of the liquor has been drawn into the system, collection of the condensate is stopped and refluxing is begun. The total time of the test has been arbitrarily established at 20 hours.

#### SUMMARY OF RESULTS

In this and in a previous bracket of experimental work the four afore-mentioned methods of scale reduction through ion exchange

have been successfully carried out on a laboratory scale. Table II is a summary of data for the most pertinent experimental runs. The Appendix contains photographs showing scaling in the heat exchanger tube by untreated liquor. Photographs of the tube after successful application of ion exchange are also included.

Analysis of liquors passed through a Cation exchanger operating either an  $H^+$  or  $Na^+$  cycle shows a substantial decrease in calcium content. Subsequent evaporation of liquors passed through a  $Na^+$  regenerated cation bed, showed a complete reduction of scaling.

Analysis of liquors passed through anion beds have indicated a marked reduction in the sulfite content. Liquors prepared in this manner have shown a complete freedom from scaling by the evaporation test.

A series of repeated runs were made on each of two resins, the Amberlite IR-120 and Amberlite IRA-400 to determine if the liquor in any manner poisoned the resin beds. The tests showed that in 10 runs, there were no indications of decreased capacity or efficiency. Figures 4 and 5 are photographs of the heat exchanger tube after tests of liquors passed through the exchanger beds during the tenth cycle. The absence of scaling is evident.

A semi-quantitative analysis of resin capacity and regenerant requirements has been determined for two of the most promising cycles with sodium chloride regeneration, (Amberlite IR-120 and Amberlite IRA-410 resins).

When examining the data, consideration must be given to the fact that the calculations are based upon semi-quantitative data taken from purely arbitrary conditions which are not necessarily optimum.

The material outlined in this report is intended to be considered as a preliminary survey of the possibilities of ion-exchange as a method of waste liquor recovery. Although the results appear to be promising, a more thorough study is necessary in order to obtain the most efficient utilization of the processes. Therefore, as a guide for future investigation, several important problems are listed below:

1. The maximum permissible ion concentration below the scaling level
  2. The intensity of scaling which may be tolerated
  3. The optimum regenerant quantity and concentration, as it is affected by point 1.
  4. The optimum flow rates in the exchange cycle
  5. The optimum volume of wash water
  6. Recycling of wash water for regeneration and/or optimum utilization
  7. Analysis of liquors for possible use in chemical recovery processes and/or for heating value
  8. Based upon the findings of the above items, make cost analyses of the more promising exchange processes.
- Consideration should be given to the value of chemical or heat recovery and/or the reuse of raw materials.

TABLE II

OPERATING CONDITIONS AND RESULTS OF  
THE PRINCIPLE EXPERIMENTAL  
RUNS

(1) Based upon actual analysis of the ion exchanged

(2) An average figure for the scale of an untreated liquor is 0.650 gms.

TABLE III

APPROXIMATE COST FOR PROCESSING THE WASTE LIQUOR  
FROM ONE TON OF SULFITE PULP<sup>1</sup>

| Ion exchanger                                 | Amberlite IR-120 | Amberlite IRA-400 |
|-----------------------------------------------|------------------|-------------------|
| Type                                          | Cation           | Anion             |
| Volume required, cu. ft.                      | 36.3             | 16.2              |
| Wash water requirement, gals.                 | 800              | 648               |
| Regenerant requirement (sodium chloride), lb. | 254-508          | 241-482           |
| Regenerant cost, <sup>2</sup>                 | \$2.25-4.50      | \$2.12-4.23       |

<sup>1</sup> 1850 gallons of 13% O.D. liquor

<sup>2</sup> The cost of sodium chloride is \$.38/100 lbs.

Figure 4

Heat Exchanger Tube After Evaporation of  
Sulfite Liquor Treated by Amberlite IR-120.  
(10th Cycle)

Throughput Volume 23.8 gal./ft.<sup>3</sup>

Figure 5

Heat Exchanger Tube After Evaporation of  
Sulfite Waste Liquor Treated By Amberlite IRA-400  
(10th Cycle)

Throughput Volume 114.5 gal./ft.<sup>3</sup>
