#### Abstract

The MAPPS process simulation and end-use performance models accurately predict the effects of process conditions on handsheet and machine paper properties for corrugating medium. The models were validated through detailed analysis of mill trial data from a MacMillan Bloedel corrugating medium paper machine and through extensive modelling of the papermaking process using MAPPS.

The major objective was to validate the capability of the system to predict a variety of end-use performance characteristics for a major paper grade such as corrugating medium. The study reveals the sensitivity of compressive and other properties to key process variables such as OCC content, refining power, press loads and calendering. The analysis shows that the PAT's model system is a much more useful tool to determine the interactions of process and product variables than standard statistical techniques alone. The simulation model is useful for both process and product development and can provide valuable insights into the effects of process and furnish conditions on product properties.

The models correlated the property data within a very high R-squared value indicating not only that the models are significant but that the data are not random. Property data were obtained on 24 reel samples and 120 sets of composite pulp samples collected at five locations over a three-day period. Good statistical agreement was obtained on both machine paper and handsheets from composite pulps. This report describes the test conditions, data analysis, modelling techniques and conclusions about the effects of processing conditions on properties. Other reports are planned which describe the models in more detail.

The sensitivity case study using the validated model determined the sensitivity (slope) of machine paper properties to each of the test variables over the maximum range of the test. These results are summarized in the following report.

The study also revealed several weaknesses in the models in the area of pressing and property development. These will require review and modification before additional validation work is undertaken. Future model validation work planned for 1991-1992 includes completion of a mill trial for multi-ply linerboard grade and initiation of a free sheet trial.

## EXECUTIVE SUMMARY

This report summarizes the results of a machine trial to validate the MAPPS Performance Attribute System for corrugating medium grades. The objective was to determine the ability of the MAPPS models to track the response of handsheet and machine paper properties, primarily compressive strength, to changes in several important process variables. The variables selected for the test were OCC content, primary and tickler refiner conditions, calender loading, third press loading and machine speed.

Statistical analysis of the data showed that the models performed well and are generally valid for this grade. Model adequacy was based on two tests, one based on measurement error and one based on model regression. Over the twenty-four reel sampling intervals, the MAPPS model tracked machine paper properties within measurement variance. This indicates that the models may be useful in predicting short term variations in properties and in determining whether variability is real or due to measurement error.

A second measure of model adequacy was based on a regression of the data against model predictions for each property. These regressions showed excellent agreement. The R-squared values for each property ranged from 0.99 to 0.998 with a confidence interval of $95 \%$. Each regression generated a single correction or multiplier for each property. Many of these correction factors were close to one, indicating the models accurately predict the mean data for many properties. The correction factors for several of the compressive properties and Gurley porosity were significantly different from 1. It is not clear at this stage whether these correction factors are universal or specific to this particular paper machine.

CD variability was a significant factor for a number of variables, such as basis weight, caliper, and density, and for several tensile variables, such as breaking length and burst factor, but was not significant for compressive or elastic properties. CD variability was not modelled in the current study but is within the capability of the MAPPS system.

Because several variables were changing simultaneously during the trial, it was not possible to determine exact measures of the sensitivity of individual properties to individual variables from the raw data. In part two of the study, a sensitivity study using the validated model determined the slope dependence of each property on the key independent variables.

Statistical tests showed that third press and lump breaker loading had no effect at the testing levels. Similarly, OCC content and machine speed had little influence on compressive properties and only a statistically weak effect on tensile properties. The absence of an OCC content effect could have been predicted

## Performance Attribute Validation Study On Corrugating Medium

beforehand by a comparison of the performance attributes of the OCC and semi-chem pulps. With the exception of fiber length and freeness, the semi-chem PAT's are very similar to the OCC PAT's indicating that a change in OCC content will have little effect on paper properties.

Of all the test conditions, calender load produced the most surprises. Calender load had a strong effect on caliper, density and elastic properties. However, the calender load effect was reduced or nonexistent on measured compressive and tensile properties. Predicted compressive properties were similarly insensitive to calender load while predicted caliper, density and elastic properties showed a similar strong influence of calender loading.

The calender influence can be explained through an examination of the models. Densification during calendering increases specific modulus but reduces caliper. Compressive properties are functions of the product of specific modulus and sheet thickness. When the calender stack is lifted, the increased caliper tends to cancel the effect of the decreased modulus and there is little effect on compressive properties as a result.

Only two minor problem areas were found in the property predictions. One area was in the predicted effect of calender loading on tensile properties. The second was in the prediction of densification in the presses on the sidedness of the sheet. These problem areas, corrective actions and future work are discussed in more detail.

# Performance Attribute Validation Study On Corrugating Medium 

## INTRODUCTION

A novel system of Performance Attribute (PAT) models has been integrated with existing and/or new mass and energy balance models to give MAPPS the ability to predict the development of both handsheet and machine-paper properties. The resulting system is capable of predicting properties of paper and paperboard grades made from a variety of wood species. The machine trial outlined in this document is designed to validate the PAT system for corrugating medium.

The concept of end-use performance modelling was developed to include the generally non-conservative properties of fibers and the fiber network as an extension to the standard mass and energy balance process models. The resulting PAT Modeling system in MAPPS has the following capabilities:

1) to predict the end-use performance characteristics of paper and paperboard,
2) to quantify the interactions between fibers and the fiber network, processing conditions, and end-use performance characteristics,
3) to provide the framework for a new approach to the solution of product quality problems,
4) to provide a platform for process optimization and control which includes both process and product quality parameters,
5) to provide the technical "first principles" basis for understanding the fundamentals of product quality relationships.

Specifically, performance attributes are composed of a set of 29 variables which describe the state of the fiber furnish or the fiber network at any given point in the papermaking process. A species data base was constructed to initialize performance attributes, and PAT models were developed to predict the effects of the various pulp and paper unit operations and operating conditions on these PAT's. Finally, product quality models were developed to use the performance attributes and the mass and energy characteristics of the process system to predict the quality characteristics of the fiber furnish and the fiber network. With this system MAPPS now can simulate quality development from the wood yard to the reel.

PAT's can be classified as component (i.e., fiber or filler) attributes or network attributes as shown in Figure 1. As fiber or filler attributes, PAT's can be categorized as composition, shape, surface area, physical properties and optical properties. Network PAT's are related to contact area, bond area, and anisotropy. Anisotropy, in turn, includes such factors as sidedness, formation, fiber orientation and stress distribution variables. Each of these variables may be affected differently, or perhaps not at all, by each pulp and paper unit operation.

For example, chemical pulping leads to a reduction in yield, kappa number, hemicellulose content, absorption coefficient and a change in other fiber tensile or physical properties. High yield or stock refining results in changes in fiber length, surface area (both internal and external), and shive content. At the paper machine, the forming operations influence fiber contacts, mass distribution, fiber orientation, etc. The wet pressing operation further increases fiber contacts and, finally, the dryer section creates the hydrogen bonded fiber network.

Using a modular approach, changes in performance attributes can be modelled separately for each of the processing unit operations. At the reel, the cumulative effects of these operations culminate with the final machine-made paper properties, calculated from the PAT's by a property module. Property calculations, however, are not limited to the end of the paper machine because the property module can also predict handsheet properties based on user-specified TAPPI testing conditions.

The models discussed above were developed from a host of literature sources and are based on a mixture of theory and experimental data. The novel nature of the modelling system, and the new concepts involved in combining many different sources of theory and experimental data into a unified system, has resulted in the creation of a completely new and expanded version of MAPPS. Thus, a validation procedure must be established so that the predictions of the new MAPPS can be systematically confirmed for each of the major paper and paperboard grades.

Previous studies, some conducted as early as 1987, showed that the new model calculations were reasonable and consistent. However, these studies did not deal with issues such as variability, trends and process sensitivity. The two-part machine trial procedure which follows has been designed to consider these issues.

## OBJECTIVES

## 1) Model Validation

In order to develop significant credibility and widespread use of the MAPPS Performance Attribute (PAT) system within the industry, it is important to demonstrate agreement of the system predictions with mill process data. This project was directed specifically to validate the system for corrugating medium. Validation is defined as "reasonable" agreement between measurements and predictions, taking into account measurement variance and other sources of error such as CD variability.

## 2) Process Variable Sensitivity

If the PAT models are found to be valid, the MAPPS flowsheet model will then be used to quantify the sensitivity of medium properties to several important independent variables such as OCC content, refining load, press load and calender application.

## SCOPE

The validation study is limited to two main characteristics: 1) reasonable prediction of short-term and long-term property variability and 2) correct prediction of sensitivity of important sheet properties to key process variables.

For purposes of this study, the validation was limited to the paper machine area beginning at the high density tanks and including the major paper machine operations such as stock preparation, sheet forming, white water recovery, wet pressing, drying and converting.

Although CD variations are expected for some properties, the model is restricted to predictions of an MD profile. A detailed CD variability study may be justified in future validation work.

Comparisons between measurements and predictions are based on both handsheet and machine paper properties. Handsheets were made from composite pulps collected at several (five) key locations in the paper machine area. Only the heavier 26 lb . handsheet data were used in the analysis because compressive properties were not determined on the lighter weight ( 13 lb .) sheets.

Validation criteria are based primarily on statistical measures of "goodness of fit" and estimates of various factors contributing to variability such as measurement error, errors in estimating process conditions and transient effects. Predictions which fall within a well-defined band around the mean measurements indicate a valid model. The band includes the average measurement error plus CD variability and errors associated with uncertainty in input data.

## PROCESS VARIABLES

The test was conducted during three eight-hour periods from 0600 hours to 1400 hours on April 3 through 5, 1990. Test conditions are shown in Table I. Variables can be broken down into three categories: (1) primary - controlled, (2) secondary uncontrolled but monitored and (3) uncontrolled or controlled but not monitored. Only variables in the first two categories will be discussed.

The original intent of the test was to change each variable about its mean value and to achieve a "steady state" between each change. In actuality, a number of variables (both controlled and uncontrolled) were changing simultaneously, and the results show the superposition of a number of variables.

Table I: Test Variables and Data Ranges

| Primary Variables | Range | Mean |
| :---: | :---: | :---: |
| 1 Percent occ, | 18-38 | 27 |
| 2 OCC Consistency, | 5.1-6.0 | 5.57 |

* Indicates properties which were compared to model predictions.

## METHODOLOGY

The validation procedure was broken down into several phases: a preliminary phase, data collection, simulation, data analysis and report generation.

## Prel iminary Phase

In the preliminary phase a MAPPS flowsheet model was developed at the appropriate level of detail and run under "typical" corrugating medium conditions to determine if the results were reasonable. The preliminary model was evaluated with best estimates for initial furnish conditions, refining, forming, pressing and calendering conditions. Preliminary evaluation focused mainly on property development, caliper changes and dewatering in the press section, freeness changes in refining, retentions and moistures in forming, and final calendered machine paper properties.

Having obtained reasonable agreement with the preliminary model and data, the most significant variables were identified and a preliminary experimental plan developed. The flowsheet model was reviewed and corrected.

## Data Collection Phase

A final plan was developed by MacMillan and the test was run. Handsheet forming procedures were developed and the appropriate tests performed. Machine paper testing procedures were developed and the data generated. Data were stored initially in Lotus spreadsheet data files and later translated into SAS (Statistical Analysis System) data files for detailed analysis and plotting.

## Data Analysis

A series of 24 MAPPS simulations were run with each simulation corresponding to a reel sample. The process simulation model and data are described in the following sections. Handsheet and machine paper properties predicted by the model were entered into individual data bases for later analysis. The data were analyzed through graphical as well as statistical techniques to break down overall variance into its components such as measurement variance, CD variability and contributions from individual processing conditions. The model validity is established through the combined analysis.

The analysis also exposed weaknesses and deficiencies in the models as well as insights into the effects of processing conditions on properties.

## Sensitivity Study

The validated simulation model was then used to determine the sensitivity of the properties to four process variables: OCC content, freeness from tickler refiner, third nip pressing pressure and calender stack loading. A sensitivity coefficient is defined as the ratio of the change of each property to a change in one of these variables. Reel 1 conditions were used as the base case. The maximum variation of each variable is based on the maximum variations used in the test.

Ideally the predicted sensitivity or slope values should be compared with estimates from the experimental data. However, in this situation where several variables were changing simultaneously, it was not possible through statistical means to determine the experimental values of the sensitivities. This points out one of the advantages of using a valid model.

## RUN CONDITIONS

Run conditions, summarized in Table VI, are broken down by day. The reel numbers 1 through 24 apply only to this study and are not production numbers. More detailed information including broke and saveall flows can be found in Appendix $I$.

## Table VI: Summary of Run Conditions (Day 1)

The data in Table VI were used as input for each MAPPS simulation run. A separate run was made for each reel. These conditions are only a portion of the data requirements for the MAPPS simulation. Additional data requirements are discussed in the following sections.

## SUMMARY OF PROCESS CHANGES

OCC flow ratio gradually increased from about $18 \%$ to a maximum of $38 \%$ on reel 10 and then dropped to $25 \%$ by the end of the test. Refiner power remained in the range of 1.5 to 2.5 hsp -day/ton except for reels 17 through 24 where power increased to 3 to 5 hp -day/ton. Tickler refiner power was approximately 0.05 except for reels 11 through 16 where it was increased from 0.11 to 0.28 hp -day/ton. Headbox CSF, one of the most important single variables, reflecting the sum total of refining changes and OCC swings, varied over a relatively narrow range from 260 on reel 4 to 335 on reel 16. Headbox freeness is also strongly dependent on fines recycle and wire retention.

The calender stack was applied on all reels except reels 7 and 8 where it was lifted. Press loading was only changed on the third press nip. The press load was 600 for reels $1-8,650$ for reels $9-16$ and dropped to 480 for reels 17 through 24. Machine speed was $1900 \mathrm{ft} . / \mathrm{min}$. for the first two days (reels 1 through 16) and then dropped to $1400 \mathrm{ft} . / \mathrm{min}$. for the third day (reels 17 through 24).

On the first day of testing, the main process changes were increasing OCC and varying calender loading (reels 7 and 8). Each reel interval was approximately 45 minutes. The total testing period for each day was thus about 6 hours. Each test was begun about 7 AM and concluded at around 2 PM. The time between the last reel sample on one day and the first reel sample of the next day was about 17 hours. This delay should have been sufficient to eliminate any transients in the system caused by deliberate process changes.

## PERFORMANCE ATTRIBUTES

This section provides a brief overview of performance attribute concepts. For a more detailed discussion of PAT's please review References 1 through 6 . Reference 1 describes the development of the system as of 1988. References 2 through 6 describe applications of the system and previous validation work. Those already familiar with performance attribute concepts may proceed to the PROCESS MODEL section.

PAT's are process variables which represent characteristics of individual fibers and the developing fiber network during the papermaking process. PAT variables apply to all areas of pulping and papermaking where fibers are found from the wood yard to
the reel. The current set of PAT variables, shown in Figure 1 , is grouped into seven categories: composition, shape, physical properties, surface area, fillers, network bonds, and network anisotropy.

Figure 1: Overview of Performance Attributes PAT's

Figure 1 illustrates the concept that paper of any type consists of fibers and other materials (non-fibrous suspended solids) formed into a network. The components of the furnish, i.e., fibers or non-fibers (fillers), have a variety of characteristics, each with a unique contribution to end-use performance and each influenced differently during the papermaking process.

Composition Attributes and Specific Light Absorption
The first three attributes, Yield (pulping yield), Kappa (Kappa Number) and Xhemi (hemicellulose to total cellulose ratio), represent the current state of the chemical composition of the fibers. These attributes can be used to account for fiber species, pulping and bleaching operations and other process steps which influence fiber composition. In this application they account for the semi-chemical pulping of the virgin hardwood as well as the chemical pulping treatments of the OCC
during its manufacture, without actually simulating these operations in detail. However, when these operations are of interest, detailed models can be added to simulate both the mass and energy flows as well as the changes in PAT's over these process steps.
$C_{k}$, the specific absorption coefficient, is placed with the composition attributes because of its relationship to color bodies and lignin.

Many of the PAT variables are initialized through the fiber property data base. This data base consists of composition, shape and tensile properties for nineteen fiber species including northern and southern US hardwoods and softwoods and eucalyptus. The data base also contains typical values for cellulose, hemicellulose, lignin, extractives and ash content for each species. There data have two major uses, 1) to initialize the flows of pulping and bleaching stream components and (2) to initialize the composition PAT's.

Initialization of component flows for a pulping type stream is straightforward because there is a direct correspondence between the data base and the components in the stream. For a wood fiber stream such as a paper stream, of interest in this application, the stream components are initialized through the fiber shape attributes discussed later.

The link between the database composition values and the composition attributes is more subtle. For any stream type, the initial yield is assumed to be that of an unpulped wood, i.e., $100 \%$ unless overridden by the user. If the yield is less than $100 \%$, a hierarchy of pulping reactions is assumed. The order of the hierarchy is removal of extractives, hemicellulose, lignin and finally alpha-cellulose. In all cases, the extractives are assumed to be removed in the form of turpentine and tall 0il. For the paper-type stream these removed components are placed in the generic dissolved components category. If the hemicellulose ratio is not overridden in the W00DO2 block, the lignin content is based on the yield and the unpulped lignin. The kappa number is then based on a direct correspondence between lignin and kappa number. If hemicellulose ratio is not overridden, the hemi-cellulose components are assumed to be reduced before lignin and the kappa number is then based on the remaining lignin.

Specific light absorption coefficient, $C_{k}$, is based on Kubelka-Monk theory and an assumed relationship between the fiber composition and the specific absorption of cellulose and lignin. $C_{k}$ is actually the average absorption of the entire furnish mixture valid at a specific wavelength of light, 457 nm . If other materials are added to the fiber stream, such as dyes or suspended solids, $C_{k}$ is updated based on standard mixing rules. In this application, $C_{k}$ and other optical properties are not considered further.

## Fiber Morphology

Fiber morphology or shape attributes are $L$, weight-average fiber length, $\sigma_{j}$, standard deviation of the length distribution, $W$, number-average fiber width, $\sigma_{W}$, standard deviation of the width distribution, JDIST, type of distribution (normal, log-normal or Weibull) and CWT, cell wall thickness. One of the most important characteristics of pulp is the wide range in these attributes, particularly fiber length. Fiber width is primarily useful in accounting for shives. CWT is required to account for the wide variations in cell wall thickness between species. The shape attributes help to account for the differences between species, refining histories, as well as cleaning and screening, and recycling effects. They are essential in tracking the fiber morphology when using pulping and bleaching streams and also provide a link to flows of individual fiber components.

As with composition attributes, the shape attributes may be initialized from the species data base or overridden with user input. The final values are used to initialize the shape PAT's and the flows of fiber components.

JDIST is a flag which defines the type of fiber length distribution applicable. Options include normal, log-normal, modified log-normal and Weibull. Only one type of distribution is assumed to apply locally. Thus, if a log-normal distribution is specified, both length and width must follow a log-normal distribution. However, JDIST may be assigned different values at different points in the flowsheet to simulate different types of furnish or process operations.

## Physical Properties

Fiber physical properties which affect end-use performance are $Z_{f}$, fiber tensile, $E_{f}$, fiber modulus; and Smod, fiber flexibility factor. $Z_{f}$ has units of breaking length in kilometers and represents the zero-span tensile strength of the sheet. The fiber tensile has a direct effect on sheet tensile strength and indirectly affects burst factor through the Page tensile and modified van den Akker burst relationships. The fiber modulus has a direct influence on sheet elastic properties and indirectly on compressive properties such as STFI, Concora and Ring Crush.

Specific Bond Strength, (SBS) is a measure of the potential bond strength when bonds are developed. In the absence of species dependent data, the same value is used for all species. Along with bond area and formation factor described later, SBS contributes to sheet strength through the Page tensile model.

## Performance Attribute Validation Study On Corrugating Medium

The fiber flexibility factor accounts for subtle changes in fiber bonding flexibility and conformability resulting from changes in cell wall composition and thickness during drying, pulping and refining. This factor is meant to account for effects not handled directly by CWT. Smod is initialized to one and changes only slightly in refining and drying. In the current application, Smod increases during drying to reflect the stiffening of the fibers as the cell wall material collapses during drying. Smod decreases during refining reflecting the swelling of cell wall components.

## Surface Area Attributes

Another important characteristic of fibers which influences bonding potential is hydrodynamic specific surface, $S_{h}$. It is well known that Canadian Standard Freeness (CSF) is directly related to hydrodynamic specific surface. While bonding and end-use performance are directly related to the more fundamental variable, $S_{h}$, the variable of choice followed in this system is CSF since it is measured directly and is readily known by mill process engineers.

CSF, $S_{h}$ and fiber length distribution are linked together within the PAT modelling system. The combination of CSF and fiber length distribution determines the specific surface area for each fiber length. Fiber length distribution is determined from the mean and standard deviation, $L$ and $\sigma_{\rho}$. Once the specific surface areas are known at each fiber length, the specific surface area for the entire distribution can be readily determined.

## Suspended Solids Attributes

Fibers are not the only significant components of the paper. For filled grades, suspended material such as fillers and extenders, which may represent $50 \%$ of the basis weight, can have a major influence on end-use performance. Attributes in this category are the average particle size, SUSL, SUSD, average light absorption coefficient at 457 nm , SCC, average light scattering coefficient; and SHP, average shape factor. These attributes play an important role in modelling filled sheet grades but are not used in this application.

## Network Attributes

As the fiber network forms in the forming section and is consolidated throughout the press section, the fundamental variables of interest are the fiber contacts for the top side and wire side represented by $S_{b 1}$ and $S_{b 2}$. These variables also take into account some of the aspects of the sidedness characteristics of the sheet but do not include effects such as wire mark. The values of $S_{b 1}$ and $S_{b 2}$ are generated automatically during the forming and pressing processes and are used automatically by the property modules. It is not really necessary to pay much attention to these
variables except to note that the higher the value of these variables the higher the sheet density, other things being equal. Also, when the sheet is dried, the fiber contact variables determine the degree of fiber bonding and the bond density. As $S_{b 1}$ and $S_{b 2}$ increase, the bond density also increases. This in turn leads to an increase in sheet strength and stiffness (modulus).

Fiber contact area is influenced by the degree of fiber conformability which in turn is influenced by pulping yield, cell wall thickness, surface area (CSF), and fiber stiffness factor, Smod. Contact area is also increased by pressing pressure and can be increased or decreased by calendering load. $S_{b 1}$ and $S_{b 2}$ are the only attributes which change during wet pressing.

## Fiber-fiber Bonds

$S_{\mathrm{a}}$ represents the bonded area developed during forming, pressing and drying. This variable has a direct influence on bond density and sheet strength. $S_{a}$ is generally proportional to the fiber contact areas discussed previously as well as to the drying temperature and moisture. As sheet moisture increases above $6 \%$, cellulose hydrogen bonds are replaced by water hydrogen bonds and $S_{a}$ decreases. This applies whether the sheet is being dried or is re-wetting. As $S_{a}$ decreases, bond density decreases, which leads to a loss in sheet strength and modulus.

Calendering conditions can influence $S_{a}$ either positively or negatively depending on the moisture and temperature conditions, the calendering load, and the thermal softening temperature of the fibers. The thermal softening temperature or glass transition temperature is a function of composition, moisture and temperature of the fibers. In summary, $S_{a}$ is a direct result of the cumulative effects of species type, pulping, refining and forming conditions throughout the process and is a direct link between these conditions and end-use performance characteristics.

## Sheet Anisotropy

Three types of non-uniformity in the plane of the sheet are accounted for. These are formation, variation of residual stresses and sidedness.

## Residual Stresses

MD, CD and ZD variability can result from a built-in stress distribution within the sheet resulting from forming and drying conditions. Two factors which contribute to this built-in stress distribution are fiber orientation and stretch due to speed differentials along the machine. Significant deviations from random orientation and significant MD stretch will dramatically increase MD/CD tensile ratio. MD stretch at failure will also decrease with increasing MD wet strain. These factors are accounted for by the two attributes, $O R$ and WS, which represent the average fiber

## Performance Attribute Validation Study On Corrugating Medium

orientation and cumulative set strain in the sheet. Fiber orientation is determined during sheet forming while wet strain is introduced as a result of the speed differentials at each pickup point in the forming section. These attributes will also affect elastic properties and compressive strength properties such as STFI, Ring Crush and combined board properties such as Concora.

## Formation

A second type of variability of great importance is formation. This type of anisotropy results from nonuniform mass distribution in the plane of the sheet. This attribute is determined completely during forming and is influenced by factors such as fiber length, forming consistency, jet-to-wire ratio and CSF. The formation attribute is not assumed to change during pressing and drying. This attribute works with $S_{a}$ to determine bond density and sheet strength. The relationships are based on the concept that the weakest link determines the strength of the sheet. Formation does not influence bulk density or porosity.

## Sidedness

The third type of variability, sidedness, is handled through $S_{b 1}$ and $S_{b 2}$ above. This type of variability is affected by forming, pressing and calendering conditions. Sidedness is one aspect of the more fundamental Z-D variability resulting from one-directional drainage and retention conditions during forming. Sidedness can be corrected through calendering by densifying one side more than the other to achieve a similar degree of smoothness on each side of the sheet. $\mathrm{S}_{\mathrm{bl}}$ and $S_{b 2}$ form the basis for modelling surface density, which may differ from bulk density. Surface density forms the basis for modelling such end-use performance characteristics as gloss, smoothness/roughness and printability. These characteristics are not important in the current application and will not be discussed further.

## Property Flag

The property flag is really not an attribute. Its purpose is to point to the appropriate group of property models. By passing this flag throughout the flowsheet as a stream variable, it is possible to point to the desired set of end-use performance models at many points in the flowsheet simultaneously without having to list it at many individual locations.

## PROCESS MODEL

The process model, shown schematically in Figures 2 through 4, is divided into three parts:

I Fiber blending and refining, II Stock preparation and cleaning and
III Forming.
Each section is discussed in detail below. For a detailed understanding of the individual models, please refer to the MAPPS technical documentation (Reference 7).

## 】 Fiber Blending and Refining

The high density storage tanks are represented by stream initialization blocks called WOODO2. These blocks serve the dual purposes of initializing both the material/energy and the performance attribute streams for the virgin semi-chem and OCC furnishes. By means of module parameters, each WOODO2 block initializes the total mass flow, composition, temperature, pressure and fiber characteristics of an entering fiber stream. Because the OCC is a true mixture of hardwood and softwood components, it is necessary to use two W00D02 blocks, one for the softwood and one for the hardwood components of the OCC. The characteristics of the hardwood component of the OCC are assumed to be close to the semi-chem hardwood. The softwood component is assumed to be similar to a southern pine.

The OCC blend is obtained by mixing the two streams in Module 4. The STOMIX module determines the mixture attributes as well as the mixture composition and thermodynamic properties of the OCC.

The virgin semi-chemical pulp is initialized by Module 1 , representing the high density chest, thickened to refining consistency by Module 5 and refined by the primary (hole) refiner (Module 7) then mixed with refined OCC in the blend chest (Module 9). OCC furnish consists of a recycled hardwood initialized by Module 2 which is then mixed with a softwood component initialized in Module 3. The OCC consists of equal portions of hardwood and softwood fibers.

Entering fiber streams 1 through 3 are initialized by specifying the total stream mass flow rate, moisture content, temperature and pressure in Blocks 1 through 3, respectively. The individual fiber flows are not specified. Instead, the individual fiber component flows are determined from the fiber length and width distributions based on either the species data base default values or user-specified values of the mean and standard deviation of length and width distribution parameters.

The default values for all PAT's are determined for each stream by specifying a wood species. WOODO2 initializes all the PAT's using the species data base which assumes that each pulp consists of fibers which have not been pulped or refined. To represent the pulping steps the fibers have been exposed to, selected PAT values are manually overridden in each WOODO2 block. For example, for the semi-chemical HW pulp, the yield, fiber length statistics, fiber width statistics, freeness and several other parameters have been overridden in Module l. Initialization values chosen for each furnish are shown in Table IV. The OCC column contains information on the hardwood and softwood components of the OCC specified in Modules 2 and 3 and the mixture values determined in the mixer block (Module 4).

Table VII: PAT Initialization Data Parameters Used in wOOD02

| Species | ```Semi-chem Pulp Hardwood``` | OCC Furnish Comp. |  | OCC Mix |
| :---: | :---: | :---: | :---: | :---: |
|  |  | Hardwood | Softwood |  |
| Fiber Length Distribution |  |  |  |  |
| Weight Average, mm | 1.4 | 1.4 | 3.0 | 2.2 |
| Standard Deviation, mm $t$. | 2.5 | 2.5 | 2.5 | 2.5 |
| Number Average, mm. | 0.02 | 0.02 | 0.04 | 0.03 |
| standard Deviation, mm t. | 2.0 | 2.0 | 1.15 | 1.65 |
| Cell Wall Thick, microns... | 1.2 | 1.2 | 1.2 | 1.2 |
| Yield, \%... | 74 | 74 | 60 | 67 |
| Kappa Number. | 46.2 | 23.9 | 185.5 | 104.7 |
| * CSF, ml.. | 656 | 150 | 667 | 316 |
| Specific Bond Str $\times 10^{-8} . .$. | 0.2 | 0.2 | 0.2 | 0.2 |
| Fiber Tensile, km........... | 10 | 10 | 10 | 10 |
| Fiber Elastic Modulus, GPa. | 4.5 | 4.5 | 4.5 | 4.5 |
| * Total Wood Flow, lb/hrx10-6 | 3.88 | 4.254 | 4.254 | 8.5 |
| Wood Moisture (fraction)... | 0.99 | 0.90 | 0.90 | 0.90 |

Notes: (1) Dry fiber flow is one minus wood moisture multiplied by total wood flow. (2) The OCC freeness was not known and the CSF values in Modules 2 and 3 were based on experience. (3) The * indicates that the semi-chem HW CSF and the total mass flows of semi-chem and OCC were varied.

The ratio of OCC to total pulp flow was varied by changing the dry wood flow rate in the OCC initialization blocks, Modules 2 and 3. Refining consistency into the refiner was adjusted by varying the discharge consistency in Modules 5 and 6 and refining load was adjusted by varying the specific power in Module 7. The specific power was set to zero in the OCC stock refiner to reflect the fact that this refiner was not used.

The apparently large standard deviation values for length and width may be explained by the fact that the terms involving the standard deviations in the distribution functions are based on the natural logarithm of the standard deviations.

The blended stock was brought to tickler refiner consistency in Module 10 and refined in Module 11. Stock was then passed to the machine chest, Module 12, which was modelled as a mixer with only one inlet stream. The pulp then passes to the stuff box which is treated as a simple splitter, Module 23 . The overflow, stream 34 , is returned to the blend chest, module 9.

Each of the fiber streams contains a range of fibers with names FINES, FIBER1, FIBER2 to FIBER10 and shive components called SHIVE1 through SHIVE3. Each fiber fraction represents a specific range of Bauer-McNett fiber lengths and a narrow range of Sommerville shive slotted screen fiber widths, all 0.15 mm or greater. Each shive component covers the entire range of fiber length but has a specific range of fiber widths greater than 0.15 mm . These dimensions are somewhat arbitrary and may be varied by changing the model coding.

For a given set of fiber statistics, mean and standard deviation, the discrete distribution is determined and represents the weight fraction of each fiber component. Each component flow is then determined directly from the total fiber flow and the fiber fractions.

Refiner feed consistency was controlled by specifying the discharge consistency in each of the thickener blocks (Modules 5, 6 and 10).

## Refining

The virgin stock and OCC are refined in Modules 7 and 8 , respectively. The stock is then combined in the blend chest (Module 9) with broke (Stream 31) and Stuff Box overflow (Stream 34). The combined stock is refined in the tickler refiner (Module 11). In the current process the OCC was not refined initially, so the specific power in Module 8 was set to zero. Other refining conditions are summarized in Table VIII.

The HYRFNI module simulates a wide range of refiner conditions from groundwood to chemical pulps. Two major categories of refiners can be modelled, chip refiners and all other types of refiners, classified in MAPPS as secondary refiners. The key difference is that chip refiners expect the inlet stream to contain chips while "secondary" refiners work with stock streams containing no chips. The freeness development and fiber length kinetic models are different for these two major types of refiners. For this application refiner type switch is set to 2 to indicate a stock refiner.

Both refiners are specified as atmospheric with minimal idle power loss. Conditions for the OCC refiner (Module 8) are not listed since this refiner was not used during the test. The user may specify refiner specific power directly or indirectly. For this study, the specific power was input directly for each case. For indirect specification, specific power is determined by means of a model based on plate gap, rotational speed, rpm, and inlet consistency.

# Performance Attribute Validation Study On Corrugating Medium 

Table VIII: Refiner Parameters (typical values)

| Parameters | Hardwood Primary | Blended Stock Tickler |
| :---: | :---: | :---: |
| Refiner type | 2 | 2 |
| Outlet Pressure | 14.7 | 14.7 |
| Power Model (Not Used) | -- | -- |
| * specific Power.............. | 1.95 | 0.05 |
| Idle Power (Fraction). | 0.05 | 0 |
| Plate Geometry (Not Used).. | -- | -- |
| Species...................... | 3 | Not Specified |
| Process Model Flag.......... | 5 | 5 |
| Distribution Type flag..... | 1 | 1 |
| Rinetic Parameters: |  |  |
| AL1 (Mean Length)......... | 30 | 3 |
| AL2 (Standard Deviation). | -1 | 0 |
| AW1 (Mean Width).......... | 0.98 | -0.5 |
| AW2 (Standard Deviation). | 0 | 0 |
| Fiber swelling parameter... | 0.001 | 0.001 |

The refiner "kinetic" parameters were tuned to agree with the generally observed discharge CSF and fiber length for the base case. These parameters determine the change in fiber length and width distributions for a given specific power load, consistency and pulping yield. The tuned parameters were then fixed and the only parameter which was changed for the remaining cases in the refiner modules was the gross specific power. The fiber swelling parameter is used to tune the fiber swelling model which uses the specific power, rpm, plate and fiber geometry, and energy per impact to determine the degree of fiber swelling. Generally, the fiber stiffness parameter, Smod, calculated by MAPPS is reduced as fiber swelling increases. However, fiber swelling conditions do not appear to be significant at the yield level used in this study.

## Other Streams

When chemical pretreatment is used, as in CTMP, the pretreatment unit generates an information stream containing data on the degree of penetration of the pulping liquor. These data are passed to the refiner by an information stream which influences refining performance. The "information streams," all represented by Stream 87 entering the refiners, are not used in this application.

In addition to the fiber discharge streams, such as streams 9, 11 and 14, refiners units generate steam and heat loss streams. These streams are generally only significant for mechanical pulping systems but are shown here for completeness.

## Adjustments

The GENPRS block, Module 40 , is placed after the blend chest to adjust selected PAT's at this stage of the simulation. GENPRS, which stands for "general process module," can function as a generic module which influences PAT's but has no effect on mass and energy flows, or it can, as it is used here, adjust PAT's up or down. No adjustments were required for the current study.

## Handsheet Properties

Handsheet properties at the discharges of the hole refiner, blend chest and tickler refiner were determined through PROPS blocks Modules 46, 47 and 48, respectively. The setup of a PROPS module is described in detail in a later section. Generally, the only parameters which are required are the stream number of interest (i.e., streams 9, 11 and 14) and the handsheet basis weight. Additional parameters which were needed for this study were the handsheet press pressure and the formation index. This was necessary because there was evidence that the handsheet forming conditions varied significantly from sample to sample. After specifying the handsheet pressing pressure and fiber formation index, the models predicted the handsheet properties more accurately. Handsheet conditions are discussed in detail in a later section.

## II Screening and Cleaning System

Refined pulp from the tickler refiner enters the Machine Chest, Module 12, and is pumped directly to the Stuff Box, represented by a total flow splitter, Module 23. In the white water silo, mixer Module 24, the refined pulp, saveall fibers (Module 50) and accepts from the secondary screen and secondary cleaner (Modules 34 and 27, respectively) are diluted with white water. Pulp consistency is controlled by means of a thickener block, Module 37, before entering the primary cleaner, Module 25. The cleaning and screening system consists of four cleaners, Modules, 25, 27, 29 and 30 , and three screens, Modules 32 , 34 , and 35 , respectively. The flow is counter-current with accepts passing back into silos and reject chests as shown. Saveall cloudy filtrate is used for dilution in tertiary cleaner chest, Module 31, and clear filtrate is used for dilution in this tertiary screen chest, Module 38. Streams 45 and 53 represent cleaner and screen sewer rejects, respectively.

All screens, cleaners and thickeners are modelled through the same HYFRAC module by specifying a switch ( $1=$ screen, $2=$ cleaner, $3=$ thickener). In addition to the unit switch, only one parameter is required for this module. For screens and cleaners, the only required parameter is the reject total flow split, while for thickeners, the parameter is the discharge consistency. Cleaners and screens fractionate the pulp removing shives and separating the fibers on the basis of aspect ratio or fiber length.

## Performance Attribute Validation Study On Corrugating Medium

When used to model a screen or cleaner, HYFRAC determines the separation of all components and, from the specified total flow split, determines the consistency of the accept and reject streams. In addition, HYFRAC determines the freeness and selected handsheet properties of the feed, accept and reject streams. Generally, rejects tend to be enriched in shives while accepts tend to be enriched in shorter fibers.

Module parameters for the screening and cleaning system are summarized in Table IX. All parameters in this section were adjusted initially to predict the generally observed level of fiber reject losses for the base case and were then fixed for the duration of the study.

Table IX

|  | Module Parameters | Piber Losses lb/hr |
| :---: | :---: | :---: |
| Consistency Controller. | 1 |  |
| Cleaners - Reject Flow split \% |  |  |
| primary. | 15 | - |
| secondary. | 10 | --- |
| Tertiary. | 10 | --- |
| Fourth......................... | 10 | 651 |
| screens - Reject Flow Split \% |  |  |
| primary. | 5 | --- |
| secondary. | 10 | --- |
| Tertiary....................... | 10 | 775 |

Typical fiber losses predicted from the system are shown in Table IX for the fourth cleaner and tertiary screen. The total losses of $1400 \mathrm{lb} / \mathrm{hr}$ were in the range of values reported by MacMillan Bloedel.

Paper machine headbox consistency is controlled in the model by module 36 which passes excess dilution water into reject chest 33.

## III Forming Section

The paper machine is modelled in four parts with four different Fourdrinier blocks, Modules 13,4142 and 45 , to represent the $C D$ variations possible across the machine. However, no attempt was made to model CD variations, and the conditions specified for each module are currently the same. The headbox stock stream is split into four equal parts by Module 43 and each Fourdrinier block represents the headbox, slice, gravity drainage forming board, foils, vacuum boxes and couch roll over one-fourth of the width of the machine. The Fourdrinier block computes the mass and energy flow and attributes of the mat, trim and white water drained and, to confirm that the property level of dewatering has occurred, an "undewatered slurry" stream is also calculated if excess slurry remains.

Since the slurry and mat streams are recombined in Module 14 to represent a single sheet of machine paper, all differences between the four CD sheets are lost in this particular model. However, by passing each CD mat stream through a parallel series of press modules, CD variations could have been tracked using the Property block (Module 22). After re-combining the CD sheets into a single sheet in Module 14, the machine-width sheet is passed through three successive press nips (Modules 15, 16, and 17). No attempt was made to model the lump breaker roll, and its effects have been assumed to be accounted for in the sheet leaving the first press (Module 15).

Parameters used in modelling the Fourdrinier are summarized in Table $X$ and typical profiles predicted by the Fourdrinier blocks are shown in Table XI.

It should be noted that no mill data were available to verify the profiles presented in Table XI and no adjustments were made to the Fourdrinier modules during the validation study. The drainage profiles are simply presented as information.

The forming section performs a variety of tasks too numerous to mention in detail. For instance, the fiber contact area, formation factor, fiber orientation and wet strain attributes are initialized and the sidedness and Z-D variability information are generated. Calculated parameters include the sheet moisture, freeness and the fiber length distribution of the mat, white water and "undewatered slurry", and the retention of suspended solids.

## White Water Recycle and Saveall

To model the saveall system, all trim and white water streams were combined into white water tank, Module 44, and then passed directly to Module 19 representing the saveall. Losses from the saveall, assumed to be negligible, were set by adjusting the split ratio of splitter module 50 to 0.001 , a loss of only $0.01 \%$. The disk saveall model generates three fiber streams, the recovered fiber (Stream 30), cloudy filtrate (Stream 29) and clear filtrate (Stream 16). The filtrate streams were sent back to the screening and cleaning to be used for dilution and consistency control and the recovered fiber was returned to the stock blending system.

## Press Section

The press section of the machine consists of a lump breaker followed by three press nips. In the model, the lump breaker is combined with the first press nip, Module 15. Each press nip is represented by a wet press model, the WPRESS block, which computes the degree of water removal and web consolidation as a function of lineal press load, the number of felts and basis weight, machine speed, press speed and fiber characteristics such as CSF, yield and CWT. The attributes changed by the presses are the fiber contact areas, $S_{b 1}$ and $S_{b 2}$. The module also determines the power requirements of the press and nip residence time but neither of these variables is discussed in this study.

* indicates parameters which were varied during the study

Other attributes calculated by the WPRESS module are the caliper of the sheet entering and leaving the nip, determined by the estimated degree of densification during pressing, and the degree of sheet consolidation relative to water removal, determined by the compressive modulus, $\mathrm{C}_{\text {mod }}$. $\mathrm{C}_{\text {mod }}$ can be determined internally but it may be necessary to override the default value of $C_{\text {mod }}$ to obtain reasonable values of the dewatering for a given caliper change. After tuning the modules to match the base case, only the third nip press loading was changed. Press conditions are summarized in Table XII.

## Drying

The pressed sheet is passed through a single dryer block, Module 18, which simulates a conventional air-hood multi-can dryer system. For more detailed simulation of the dryer system, multiple dryer blocks could be used. In each case, the steam flow was varied by hand to achieve the desired dry sheet solids of approximately $93 \%$ while holding steam pressure and air flow constant. The dryer input parameters are summarized in Table XIII.

Table XIII: Dryer Conditions

| Steam Economy. | 0.5 |
| :---: | :---: |
| Blowthrough Ratio | 0.10 |
| Steam Pressure Drop | 3.00 |
| Web temperature Ris | 4.00 |
| Leakage Air Ratio. | -0.02 |
| Room Temperature | 28.0 |
| Room Humidity. | 0.85 |
| Electrical Power Coefficient | 1.00 |
| Web Stretch (Speed Differential), \%. | 1.3 |

The total, cumulative MD stretch of $1.3 \%$ was assumed to occur in the section. This stretch was one of the key factors contributing to the predicted MD/CD tensile and modulus ratios.

## Performance Attribute Parameter Adjustments

Module 49 is a GENPRS or general purpose simulation block which can be used to modify PAT's on a relative basis. In this particular application, two variables, contact areas $S b_{1}$ and $\mathrm{Sb}_{2}$, were decreased by 10 and $30 \%$, respectively. This adjustment was required to reflect the over-prediction in the densification of the sheet which occurred during pressing, particularly on the top side of the sheet where $\mathrm{Sb}_{2}$ increased from 4 to 18 while the contact area on the wire side, $\mathrm{Sb}_{1}$, entering with a value of 4.26 , did not increase at all.

Because of the loss of fines during the initial phases of drainage, the hydrodynamic specific surface of the wire side of the sheet was significantly lower than that of the top side and the effective freeness and fiber length were significantly higher. The top side of the sheet approached the average fiber length and freeness of the entering slurry, 0.50 mm and 415 ml , respectively, while the wire side fiber length and freeness were 1.55 mm and 611 ml , respectively. Since the caliper change predicted in the press and property modules (WPRESS and PROPS) depends on the change in fiber contacts averaged over the top and bottom of the sheet, the excessive increase in $\mathrm{Sb}_{2}$ increased the average contact area and the average bond area, $\mathrm{S}_{\mathrm{a}}$. This resulted in a prediction of excessive sheet density and properties such as tensile strength and modulus which depend on either sheet density or bond density. By correcting $S_{b 1}$ and $S_{b 2}$, the entire system of properties was adjusted to more accurately reflect the mill data.

In retrospect, the sidedness differences predicted by the model can be seen to be a function of the large quantity of fines recycled within the white water system. These fines significantly reduce the freeness and fiber length at the headbox from the average of the fiber furnishes, and the characteristics of the final sheet reflect the selective retention of fibers, particularly fines, during forming. The forming model predicts that the retention of fibers increases from the bottom to the top of the sheet, resulting in higher fines retention as the basis weight develops. Thus, the top of the sheet retains most of the fines present in the headbox slurry while the bottom is nearly devoid of fines and the model makes no provision for migration of fines between the layers. However, the average contact area is assumed to be an average of the typical level of fiber contact throughout the thickness of the mat and is in good agreement with the average fiber length and freeness values carried in the PAT stream for the mats which are 0.76 mm and 544 ml .

In the future, this modelling problem can be reduced by reducing the sensitivity of the compressibility model to CSF. Alternatively, a new adjustable parameter could be added to the press model to allow the user to adjust the sensitivity of the compression to CSF. A similar approach would also be necessary for any other module which densifies the sheet, such as the calender block. These options are discussed in more detail in the section on FUTURE WORK (Module Modifications).

## Calendering

To represent calendering, the medium (Stream 28), at $93 \%$ dryness is sent through a single nip calender, Module 51, to the reel.

The calender changes sheet caliper, and bulk and also influences sheet bonding levels. The calendering effect is strongly dependent on nip loading and the response of the fibers to loading and, in turn, bonding or debonding behavior depends on the relationship between the sheet moisture and temperature and the thermal softening temperature of the fibers. Because the nip loading was not known, the load used in the simulation was tuned to $15 \mathrm{lb} / \mathrm{in}$ where the observed caliper under load and without load was in reasonable agreement with the mill data. The
calender model considers heat transfer in the nip and on the roll surface as well as the effects of wrap geometry, machine speed, roll temperature, roll radii, sheet basis weight and speed differentials and also allows for additional moisture addition by adding a steam or water stream.

The input parameters for the calender block are summarized in Table XIV. Calender speed and loading were varied during the study. The calender loading was set at 15 1b/in for reels 1 through 6 and zero for reels 7 and 8. For reels 9 through 14, loading was gradually increased to 15 to reflect the apparent transitional change in caliper, density and modulus after the load was reapplied. Although thermal transients are not considered in the model, these effects could be simulated in the future by assuming roll temperature increases gradually after reapplying the load.

Although sheet basis weight measured at the reel is known to fluctuate, an assumed average value of $0.117 \mathrm{~kg} / \mathrm{m}^{2}$ was used for the calender calculations. CD basis weight variability could also play a roll in the application of pressure to the sheet and, in the future this variation could be taken into account by the addition of multiple sets of presses and calenders to track the CD basis weight and PAT's through the machine.

The wrap configuration flag was set to 0 to indicate that the sheet passes directly through the nip without a roll wrap. No MD sheet strain or change in orientation was assumed for the calender nip as all MD strain was lumped into the dryer section. The compressibility parameter was adjusted to increase the nip intensity factor to fit the initial caliper levels of the calendered sheet at the assumed low nip loading. Since both the compressibility and the loading affect caliper and density, no unique combination of these parameters can be determined unless the actual lineal loading is measured.

## Broke System

The recycle of broke was modelled by splitting off a portion of the calendered medium using splitter Module 20. The percentage of broke was varied to match mill conditions and the broke was mixed with other furnish in the blend chest, module 9.

## Property Calculations

All property calculations were performed by a PROPS block. The PROPS block computes a set of handsheet and machine paper properties for a specific stream using the PAT and mass flow information in the stream. Valid handsheet properties can be determined on any fiber-containing stream in the flowsheet, but paper property predictions apply only to the formed, pressed, and dried sheet.

To calculate machine-made paper properties, the sheet basis weight must be specified as a parameter in the PROPS block or, alternately, the machine speed and width must be specified elsewhere. For handsheet properties, the handsheet basis weight must be specified in the PROPS block. Properties calculated by PROPS are shown in Table XV.

## Machine Paper Properties

Machine paper properties were predicted for the dry calendered medium, Stream 103, by using PROPS Module 22. Although Module 22 was used to predict both handsheet and machine paper properties, the machine paper properties are of primary interest at this location and are discussed in later sections. All measured and predicted machine paper properties are listed in Appendix II.

Machine paper properties are based on the PAT values in the stream of interest and the basis weight. The basis weight may either be specified or determined from the stream flow rate and the specified machine width and speed supplied as module parameters.

## Handsheet Properties

Five PROPS blocks, Modules $46,47,48,52$ and 53 , were used to predict handsheet properties for the hole refiner discharge (Stream 9), blend chest discharge (Stream 11), tickler refiner discharge (Stream 14), the headbox (Stream 55), and the broke tank discharge (Stream 31), respectively. Handsheet properties are dependent upon the component PAT values (i.e., fibers and fillers) and on handsheet formation factors such as pressing pressure, formation index and fiber orientation. This information can be provided by the PROPS module parameters or as a backup; default values will be assumed. PROPS Module parameters specified for each case in the study are shown in Table XVI. The complete set of handsheet properties, both measured and predicted, is listed in Appendix III.

Table XVI: Input information to PROPS

| Handsheet Fiber Orientation. | 1.0 (random) |
| :---: | :---: |
| Wet Strain | $1.0 \%$ |
| Pressing Pressure | Variable (20-50 psi) |
| Formation Fa | Variable (0.5 to 1.0) |
| Basis Weight | Measured input |

## DATA ANALYSIS

Assumptions which apply to the analysis of the data can be summarized as follows:

1) Transient process data can be analyzed using the steady-state MAPPS simulation program.
2) Data which were not known can be estimated.
3) Input data conditions obtained from the mill were assumed to be accurate.
4) Only variations attributed to the primary variables were analyzed.

## Testing Variability

Testing replicates, varying from 10 to 20 on each sample resulted in a distribution of measured values. The number of replicates was higher for tests such as concora which have greater variability or lower reproducibility. For each reel, the standard deviation of each distribution was determined about the mean value for each test property. The average of these values over all 24 reels was then used as the overall measure of testing variance for each property. The standard deviation of
the measurements is summarized in Table XVI. Measurement variances could not be determined on variables such as density, basis weight and caliper, which had only a single measurement.

Table XVIII summarizes statistical data relating to CD variability (Rolls) on each paper property. Data include the maximum value (Max), minimum value (Min), and Mean for each CD position, indicated by roll positions 1 through 3 . The table measures the overall variations which occurred during the tests and these variations are based on the average test values, rather than the individual test total variation for each sample. The mean values indicate the average $C D$ variability in the data and indicate that, on the average, the $C D$ variability is within individual test measurement variances and, therefore, is not statistically significant. However, visual inspection of the data over portions of the test groups indicates that certain variables may exhibit some meaningful CD variability. These are discussed in a later section.

Table XVII: Measurement Variance

|  | Std Dev | Number of Tests | T-Test | 90\% Confid Interval 2 std Dev |
| :---: | :---: | :---: | :---: | :---: |
| MD Tensile, km. | 0.39 | 10 | 1.812 | 0.78 |
| CD Tensile, km........ | 0.188 | 10 | 1.812 | 0.38 |
| MD stretch, \%.......... | 0.19 | 10 | 1.812 | 0.38 |
| CD stretch, \%. | 0.425 | 10 | 1.812 | 0.85 |
| Burst Factor. | 2.33 | 10 | 1.812 | 4.66 |
| MD Modulus, GPa........ | 0.155 | 10 | 1.812 | 0.31 |
| CD Modulus, GPa | 0.112 | 10 | 1.812 | 0.22 |
| Caliper, mils. | 0.39 | 1 | 6.314 | 0.78 |
| Gurley Porosity, \%.... | 3.07 | 10 | 1.812 | 6.14 |
| Concora, lb........... | 3.6 | 10 | 1.812 | 7.2 |
| MD Ring Crush, 1b/6 in | 6.2 | 10 | 1.812 | 12.4 |
| CD Ring Crush, $1 \mathrm{l} / 6$ in | 3.2 | 10 | 1.812 | 6.4 |
| MD STFI, lb. | 1.9 | 20 | 1.725 | 3.8 |
| CD STFI, lb. | 1.6 | 20 | 1.725 | 3.2 |
| Moisture, \%. | 0.38 | 5 | 2.015 | 0.78 |

A complete list of machine paper properties (measured and predicted) may be found in Appendix II.

Although statistically the means do not vary significantly across the machine, plots of the data against reel number show that some of the variables such as basis weight, caliper, density and tensile strength, may exhibit a persistent CD bias. In some cases, the CD bias lasts only one shift and then shifts to a different but also consistent bias on another day. In cases where CD bias is not visually obvious, the overall statistics are based on the pooled data for all rolls.

## Performance Attribute Validation Study On Corrugating Medium

A comparison of the overall variation with the average measurement error (standard deviation) indicates that the overall variation is not significantly greater than the measurement variation. For example, the MD tensile standard deviations for rolls 1 through 3 are . 285, . 317 and . 394 , respectively, while the average measurement standard deviation is 0.39 . The results are similar for the CD tensile.

Table XVIII: Machine Property Data Summary CD Variability

Qualitative Data Comparisons

Property comparisons are divided into two parts: Machine Paper Properties and Handsheet Properties.

## Machine Paper Properties

Machine paper property data are listed in Appendix II. For analytical purposes, the properties are plotted against a "reel number" in Figures 5 through 19. Each figure shows the predicted values and one or more sets of measured values. Where more than one set of measured value is available for a reel, the values shown correspond to tests at roll positions 1 through 3 , indicating $C D$ variability may be significant. Those properties with only a single set of measured values show all rolls and sets for each reel using the same symbols. CD variability was not significant for these properties.

## Basis Weight

Figure 5 indicates the model tracked machine paper basis weight reasonably well with the exception of reels 3,8 , and 11 through 13 . The basis weight was controlled in the simulations by adjusting the amount of broke recycle, i.e., by varying the total split fraction in Module 20. By adjusting the broke flow after the calender, it was possible to change the basis weight while maintaining constant overall production. However, the broke adjustment was accomplished by trial-and-error, and the predicted results indicate that a couple of reels were not tuned to the observed basis weight.

Basis weight varied across the machine in a consistent fashion throughout the trial as shown by Figure 5. Basis weight for roll 2 was generally lower than that for rolls 1 or 3. However, the model was not tuned to predict a variation in basis weight in the cross machine direction due to limitations in the size of the MAPPS data file and lack of detailed information on the machine design. The model did contain four separate paper machine modules (Fourdrinier modules 13, 41, 42 and 45). If to complete the CD model each of these could have been adjusted to predict higher retentions on the outside of the reel compared to the center of the reel it would have been necessary to add corresponding presses, calenders and PROPS blocks for each CD section of the sheet. This added computational burden was not considered necessary for the purpose of the study, i.e., to validate the MAPPS module database.

Basis weight showed a downward trend during the later half of the test but did not appear to coincide with changes in any of the major variables changed during this period, i.e., OCC content and machine speed. A reduction in broke flows is one likely cause of the gradual drop in basis weight. The predicted retention profiles did not show much sensitivity to machine speed.

Since most properties are independent of basis weight, any error in prediction of basis weight will have little direct effect on the prediction of other machine paper properties. Exceptions are the compressive properties which are strongly dependent on caliper. Since caliper is directly related to basis weight at a fixed density, the basis weight variations will affect compressive properties.

## Sheet Density

The machine paper density profiles, Figure 6, show good agreement between the measured and predicted values with the possible exception of reels 11 through 16 where the model predicts densities that are too high. The most obvious feature of the profile is the change caused by unloading the calender for reels 7 and 8 which the model tracks very well. Both the measured and predicted density are higher before the calender stack is lifted than after it is lifted. Although the model seems to predict the same average density level before and after reels 7 and 8 , the measured density seems significantly different. The measured data show a fairly consistent, although weak, CD profile with roll 1 density consistently lower than that of rolls 2 and 3. Measured density also fluctuates significantly during the first 6 reels while the model tracks through the center of the data, and there is no obvious explanation for this fluctuation. It is interesting to note that reel-to-reel variations after the calender is reapplied are considerably lower.

Plots of density against several of the major independent variables showed no obvious direct correspondence between density and these variables (other than calender stack loading). Statistical analysis of the data described in detail in later sections confirmed these observations.

## Caliper

Figure 7 shows predicted dry sheet caliper was in good agreement with the measured values from IPST. The most salient feature of the caliper plot is the sharp increase for reels 7 and 8 when the calender stack was lifted. The caliper obviously reflects changes in basis weight and density described previously, and good agreement in these variables implies good agreement in predicted caliper. Other features observable from the figure are the weak CD profile and the different levels of caliper before the stack is lifted (reels 1-6) and after the stack is reapplied (reels 9 through 24). A general downward trend in caliper can also be detected from reels 13 onward. The model tracks these trends quite well throughout the test.

The caliper predicted by the PROPS module is based on a bone dry basis weight and so does not include the small effects of moisture fluctuations in the sheet. However, the tests (measured values) were conducted at conditioned moisture levels at 50\% humidity and should have had only a minor effect on caliper.

## MD Tensile Strength

The MD tensile profiles shown in Figure 8 indicate that the model followed the data very well except when calender loading was removed where the model predicted a drop in strength which was not observed. During the study MD tensile appeared to have two basic levels, approximately 5.8 to 5.9 km for reels 1 through 11 and approximately 6.3 for reels 12 through 16 . A similar trend can be seen in the CD tensile profiles discussed next. The model did not predict the plateau at the same time as the measured results and tended to be lagging in phase. This behavior may be somewhat fortuitous due to the fact that the model assumes steady state conditions and there was no conscious attempt to correct the data for time delays or process lags.

The differences between the average $M D$ tensile and model values was 0.2 to 0.4 km during this plateau period, which is within experimental error. It does not appear that the change is due to a shift in MD/CD tensile ratio, as discussed in a later section.

Possible reasons for the differences in measured and predicted calender loading effects are discussed in the section on individual variable effects (Calender Loading).

## CD Tensile Strength

Figure 9 shows that the model tracks the CD tensile within the experimental error of 0.38 km . As with MD tensile, however, the discrepancy is relatively high for reels 7 and 8 where the model predicts a strength loss when the calender stack is lifted. Examination of the data shows a very significant CD profile which tends to drop for roll 3, particularly when machine speed dropped over reels 17 through 24 . CD tensile

## Performance Attribute Validation Study On Corrugating Medium

tended to increase during reels 12 through 16 . The causes of the discrepancies shown for reels 7 and 8 are discussed in the section on Calender Loading Effects.

## MD/CD Tensile Ratio

Table XIX and Figure 18 summarize the general trends for the measured and predicted tensile ratio.

Table XIX: Comparison of Measured and Predicted MD/CD Tensile Ratio

|  | Minimum | Maximum | Mean | std Dev |
| :--- | :---: | :---: | :---: | :---: |
| Measured | 2.08 | 2.69 | 2.35 | 0.115 |
| Predicted | 2.30 | 2.42 | 2.39 | 0.023 |

These data show that the model predicted the average tensile ratio very accurately and indicates that the MAPPS module assumptions about the degree of wet stretch and fiber orientation were reasonable. The fact that the predicted variations in tensile ratio are lower than the measurements can be explained by the wet strain and orientation. The major contributors to the ratio were assumed constant throughout the test while the measured data reflect the effects of large changes in machine and press speeds. Other contributions to variability, such as shrinkage and loading in the dryer section, are not accounted for in the model.

MD/CD Modulus Ratio
The MD/CD modulus ratio, a measure of the fiber stiffness anisotropy, is also influenced by fiber orientation and speed differentials, and shrinkage. Again, the agreement between measured and predicted values is very good on the average (Table $X X$ ). For reasons stated above, the model predicts less variability than is observed. The mean measured modulus ratio is nearly identical to the mean tensile ratio while the predicted modulus ratio is somewhat lower than the value for the tensile ratio.

Table XX: Comparison of Measured and Predicted MD/CD Modulus Ratio

|  | Minimum | Maximum | Mean | std Dev |
| :--- | :---: | :---: | :---: | :---: |
| Measured | 1.87 | 2.77 | 2.36 | 0.160 |
| Predicted | 2.05 | 2.19 | 2.15 | 0.021 |

## MD Stretch

Figure 10 shows that predicted MD Stretch is consistently higher than measured values by a nearly constant factor. For measured values, there is considerable variation across the machine as well as within reels as indicated by the wide bands connecting points at the same reel number.

The effect of lifting the calender on the measured MD stretch is not seen on reels 7 and 8. Again the calender appears to have little or no effect on straining the sheet or on the normal bonding characteristics which influence stretch at break. However, the average value starts out lower on day 2 (reel 9) and then increases significantly by reel 12. The highest values are seen for reel 18 just after the beginning of day 3 . There is a gradual downward trend in stretch throughout day 3 at the lower machine speed.

The model predicts that stretch should not really change much over reels 1 through 6 but drop significantly for reels 7 and 8 as a result of less bond development in the absence of calender load. The stretch does not return to the previous levels for reels 9 and 10 because the simulated stack loading was not immediately reset to 15 PLI, as with reels 1 through 6, but was increased in steps. The 15 PLI stack loading was set, the predicted stretch was at or above that of reel 1 through 6 .

## Burst Factor

Burst factor profiles, shown in Figure 11, show trends similar to breaking length as expected. The burst factor model, a modified version of the van den Akker model, assumes that burst is a function of the geometric mean of the MD and CD tensile strength and the MD stretch, as follows:

```
\(B F=\) Constant \(* S T R\left(Z_{\text {md }} Z_{c d}\right)^{1 / 2}\)
```

where

```
BF = burst factor
STR = MD stretch
Z = Breaking Length
```

The model suggests that BF will vary directly with MD stretch. Comparing the figures for tensile and stretch with burst, it appears that burst values on day one do vary directly with tensile and stretch values. BF starts out low on day 2 (reels 9 and 10) and then increases to a general maximum around reels 12 or 13 and, on day 3, a general downward trend in BF, again coinciding directly with tensile and stretch.

Although not statistically significant, there is visual evidence of CD variability in $B F$, as shown in Figure 11. As with tensile and stretch, there is no apparent effect of calender stack loading shown by the model. There is little visual evidence of a consistent $C D$ burst profile.

The general coincidence of the four tensile properties indicates that the measured trends are real and not random, and the general agreement of the model with the measured data suggests that the trends are predictable. However, there are no data to suggest what may have happened over the 16 -hour period between the end of day 1 and the beginning of day 2 to cause all four tensile properties to be lower than the previous day. Particularly puzzling is the fact that the paper density decreased at the same time that tensile strength increased toward a maximum at reel 13.

Except for the effect of calender loading where the models predict a drop in burst, the models tend to predict burst somewhat high. However, the model predictions still lie within a band defined by the combined variability in burst due to measurement error and CD variability. The measurement variability is discussed in a later section.

## MD Elastic Modulus

The MD Modulus profiles shown in Figure 12 clearly indicate the close correspondence between measured and predicted values with a small but consistent offset of about 0.3 GPa which is comparable in magnitude to the measurement variance. The most important feature of the data is the effect of calender loading, which is consistently predicted by the model. Unlike the tensile properties, the modulus values start out day 2 at about the same levels as the end of the day 1 before the calender stack was lifted. The modulus tends to increase to a maximum at about reel 15 toward the end of day 2 . There is a generally lower level of modulus for day 3 whose dominant variable is the lower machine speed. These lower levels coincide with the lower density levels as predicted by the models.

The property development models are based on a theory that there is a general correspondence between sheet densification and bond formation during the papermaking process up until the sheet is dry. Increased density leads to increased bond density, relative bonded area and, other things being equal, increased strength and elastic properties. The calender model is based on a theory that additional densification during calendering can either increase or decrease strength by creating additional bonds or by breaking existing bonds. The bond formation/bond breakage process is proportional to the degree of densification and is controlled by the moisture and temperature of the sheet in the calender. It is generally observed that increased densification leads to strength loss and a decrease in modulus. Only rarely, as with glassine to which moisture is added, is a strength increase observed. Also there is substantial evidence that modulus and strength are both governed by bonding levels and should therefore behave in the same way with densification.

## CD Modulus

CD modulus profiles shown in Figure 13 also indicate a good level of tracking between the model and the measured values with a nearly constant offset. This offset is discussed in more detail in a later section. The calender effect is the dominant effect predicted. The modulus levels at the beginning of day 2 (reels 9 through 1l) are lower than at the end of day 1 as seen with the tensile properties and in slight contrast to the MD modulus. The general levels of CD modulus also tend to peak toward the end of day 2 . There is a slightly lower modulus level throughout day 3 at the lower machine speed, which is consistent with the generally lower density levels on day 3.

## Gurley Porosity

Gurley porosity (Figure 19), which is inversely proportional to sheet porosity, follows several swings throughout the three-day period. The lowest Gurley, or highest sheet porosity, corresponds to the low calender stack loading as predicted by the model. Here the predicted Gurley tends to track density while the measured Gurley tends to track density and other variables as well. Porosity is generally lower on day three while density is lower, which is contrary to the effect predicted.

The effect of calendering on Gurley appears to be stronger than predicted. Since the model assumes porosity is proportional to bulk density, the effect of calendering, which may be mainly a surface effect, could lead to an under-prediction of the effect of calendering. In other words, if the calender tends to increase the surface density more than the bulk density, the porosity measurement, which should be more sensitive to surface porosity, should be more strongly affected. This suggests that the Gurley model should be based on surface density rather than bulk density and would be consistent with the gloss and smoothness models which are also based on surface density.

## Compressive Properties

## MD and CD STFI

The MD and CD STFI data do not show a significant trend throughout the three-day period as shown in Figures 14 and 15. The model's predictions tend to show a similar insensitivity to most variables except for a downward blip for one reel with the calender backed off. The variations in the data are less than the measurement variance indicating that there are no significant variable effects, and the offset between the model and measurements is consistently about $1.5 \mathrm{lb} / \mathrm{in}$, which is within experimental error. The statistical analysis, which is discussed in the validation analysis, shows that with the correction multiplier for MD and CD STFI taken into account, the model fits the data extremely well.

It is interesting to note that STFI was not strongly affected while modulus was. Here the theory provides some insight. The model for STFI stiffness is related to the product of MD and ZD modulus and the sheet thickness. The moduli, as already demonstrated, are directly related to the density and inversely related to the thickness. Also, the moduli contain a strong linear density component but are basically nonlinear over a large range. Therefore, one would expect qualitatively that a variable which increased caliper would have the opposite effect on modulus and no effect on STFI, consistent with the behavior seen throughout the test.

## CD Ring Crush

Data for both MD and CD Ring Crush were obtained, but only CD Ring Crush was modelled and analyzed. Although CD Ring Crush behaves very similarly to STFI, the measurement errors indicate that Ring Crush, and CD Ring Crush in particular, is highly variable, as shown by Figure 16. With a $6.4 \mathrm{lb} / 6 \mathrm{in}$. variance due to measurement error, the model predictions fall close to the lower end of the confidence range. However, if a constant correction factor is used as discussed in a later section, the predictions fall well within the $90 \%$ confidence band.

Ring Crush levels were about the same at the end of the trial as at the beginning even though the OCC content had increased by 7\%. This and other evidence indicates that OCC has little effect on compressive properties. Machine speed appears to have little effect also. Lower ring crush for the period when the stack was lowered indicated there is some sensitivity to calender load and the model predicts a drop for reel 8 but little effect for reel 7 . The effect of calender loading on compressive properties is discussed in more detail in the following sections.

## Concora

It is apparent from the concora profiles of Figure 17 that this property is also highly variable. However, the model predictions, while offset by about $25 \%$ (high), track the changes in level consistently. The model for concora is based on a relationship to flat crush which is in turn related to STFI. Thus the predictions for concora should be similar to STFI. The measurement variance for concora is 7.2 1 lb and the predicted values are generally slightly outside the upper limit of the confidence range without correction. Given a constant correction factor (multiplier), discussed in later sections, the predictions fall well within this confidence region.

The general agreement between the measured data and the model predictions for concora shows that the basic elements of the model system form a consistent framework. Calender loading appears to have some effect on concora, although primarily on reel 8. This is likely due to the fact that concora and, by implication, STFI and Ring Crush, are influenced by basis weight variations more than other variables, and the basis weight is strongly correlated with caliper or sheet thickness. However, since density is generally independent of basis weight, modulus is (or should be) relatively independent of basis weight. Thus basis weight
and caliper increases should also increase concora provided density remains the same. However, if density decreases, i.e., when the calender stack load is removed, the density and modulus effects may overwhelm the caliper increase, perhaps causing a decrease in concora.

## SUMMARY OF VARIABLE EFFECTS ON MACHINE PAPER PROPERTIES

## OCC Content

OCC concentration varied from $18 \%$ to $36 \%$ during the test but had a relatively minor affect on compressive properties. The reel-to-reel variability observed during the first 16 reels, over which OCC varied, may have been influenced by changes in semi-chem freeness and refining conditions which were occurring at the same time.

The MAPPS models show that two factors, fiber characteristics and caliper/modulus, contribute to the relative insensitivity of compressive properties to OCC content. Fiber characteristics do not change significantly as OCC content changes. Average fiber length does change gradually but this effect is masked by other variables, particularly CSF.

The second factors, caliper and modulus, tend to have opposite effects. Conditions which influence density tend to have opposite affects on modulus and caliper. Because the modulus and thickness occur together in the basic compressive strength models for STFI and Flat Crush, variables which tend to increase density and modulus tend to decrease caliper, provided basis weight is under good control. Deviations between predictions and measurements were most pronounced when basis weight varied, resulting in larger changes in caliper that were not reflected in modulus.

## Calender Load

Although the calender stack loading was known on only two reels (7 and 8) where it was zero, the calender appears to have influenced many of the properties, both before and after these reels.

As might be expected, the calender stack loading had a significant affect on density, caliper and elastic moduli. However, the affect on sheet stiffness was generally the opposite of what is normally seen for grades such as newsprint where stiffness and strength tend to decrease with increased load. In agreement with measured data, the compressive property models predicted that when the stack was pulled the increased caliper would cancel the decreased modulus resulting in little observable effect of calender stack loading on compressive properties such as STFI, Ring Crush and concora.

From the models, one might predict that the $M D / C D$ ratio of the sheet could have been affected by the calender stack loading, possibly as a function of stretch or stress relief. However, the measured properties did not support this conclusion.

After reel 8, the modulus did not return to its previous levels, indicating that the stack may not have been returned to the original loading and/or the temperature/load levels were not densifying to the earlier levels. To predict the observed effect, the load levels in the model were increased in two stages over reels 9 through 12 up to 15 pli. However, since the loading was not known at any time during the test, the model adjustments could not be verified.

Another observed anomaly was that the desired breaking length and burst factor were relatively insensitive to the release of calender loading, while the models predicted significant decreases in these properties.

Using the unverified calendering conditions, the models predicted that the calender densified and increased internal bonding in the sheet. When the calender stack was lifted, both sheet density and the bond density decreased, resulting in a drop in elastic moduli, breaking length, and burst factor. Because the measured strength did not decrease, the data did not support a change in breaking length and, therefore, burst factor, indicating that the actual levels of bonding were not significantly affected by loading under the relatively mild conditions used. This result may imply that the modulus is not a function of bond density but only of actual bulk density.

Table XXI below shows the statistical effect of calender stack loading on machine paper properties. $N$ indicates the number of data points for each condition and the minimum, maximum, mean and standard deviation values are shown for each variable, with the calender stack on or off. It may be concluded that the mean values average the effects of other variables while the standard deviations indicated the variability about the mean due to other effects such as refining, pressing, OCC and machine speed.

The caliper, density, $M D$ and $C D$ moduli, and ring crush change significantly with calender stack position (on or off). Density increases by $0.08 \mathrm{~g} / \mathrm{cc}$ or $16 \%$ with calendering, as a result of the caliper change. Surprisingly, modulus increases significantly, indicating that bonding increases in the calender nip. This effect was unexpected since the load was low and the sheet was relatively dry. In fact much of the literature shows the opposite trend, i.e., a decrease in modulus and strength due to dry calendering.

As a result of stack loading, MD modulus increased by about 0.9 GPa , approximately $30 \%$, while CD modulus increased by 0.42 GPa , approximately $25 \%$. The CD ring crush increased by $6.7 \mathrm{lb} / \mathrm{in}$ (25\%) and is comparable to the measurement standard deviation discussed below, an insignificant change. Concora changed less than the measurement standard deviation and was not significant at $90 \%$ confidence.

Mean tensile properties such as breaking length and burst factor were independent of calender loading, differing by less than the average measurement standard deviation. This result indicates that there was little, if any, net bonding or debonding occurring due to the calendering operation.

Table XXI: Effect of Calender Stack on Average Medium Properties

| Property | N | Minimum | Maximum | Mean | Std Dev |

## Machine Speed

Comparisons of machine paper properties at the two test machine speeds of 1400 and $1900 \mathrm{ft} / \mathrm{min}$ are shown in Table XXII, with 75 data points at $900 \mathrm{ft} / \mathrm{min}$ and 39 data points at $1400 \mathrm{ft} / \mathrm{min}$ for each property. Again, it may be concluded that the mean values average variations such as calender stack loading, refining and press loading while the standard deviations include variability due to these and other effects.

## Table XXII: Effect of Machine Speed

| Property | N | Minimum | Maximum | Mean | Std Dev |
| :---: | :---: | :---: | :---: | :---: | :---: |
| MD Modulus, GPa |  |  |  |  |  |
| 1900 | 75 | 3.41 | 4.86 | 4.30 | 0.38 |
| 1400 | 39 | 4.14 | 4.54 | 4.39 | 0.10 |
| CD Modulus, GPa |  |  |  |  |  |
| 1900.. | 75 | 1.30 | 2.38 | 1.82 | 0.21 |
| 1400. | 39 | 1.67 | 2.17 | 1.90 | 0.15 |
| MD Tensile, km |  |  |  |  |  |
| 1900. | 75 | 5.52 | 6.75 | 6.08 | 0.33 |
| 1400. | 39 | 5.07 | 6.03 | 5.72 | 0.21 |
| Burst Factor |  |  |  |  |  |
| 1900. | 75 | 26.51 | 33.45 | 29.60 | 1.41 |
| 1400. | 39 | 25.61 | 30.35 | 27.85 | 1.14 |
| Caliper, mils |  |  |  |  |  |
| 1900. | 75 | 7.42 | 10.02 | 8.43 | 0.56 |
| 1400. | 39 | 7.95 | 8.34 | 8.11 | 0.12 |
| Concora, 1b |  |  |  |  |  |
| 1900 | 74 | 47.70 | 63.93 | 53.13 | 2.97 |
| 1400 | 39 | 50.20 | 59.60 | 54.57 | 2.19 |
| MD STFI, lb/in |  |  |  |  |  |
| 1900...... | 39 | 21.22 | 23.67 | 22.68 | 0.61 |
| 1400. | 75 | 19.55 | 25.23 | 22.75 | 1.08 |
| CD STFI, lb/in |  |  |  |  |  |
| 1900. | 39 | 12.61 | 15.30 | 14.30 | 0.53 |
| 1400. | 74 | 12.00 | 16.77 | 14.60 | 0.59 |
| Ring Crush, ib ${ }_{\text {R }}$ |  |  |  |  |  |
| 1900. | 39 | 23.53 | 42.40 | 34.81 | 4.39 |
| 1400. | 75 | 19.48 | 43.23 | 31.35 | 5.39 |
| Density, g/cc |  |  |  |  |  |
| 1900. | 75 | 0.51 | 0.67 | 0.59 | 0.04 |
|  | 39 | 0.57 | 0.61 | 0.595 | 0.01 |
| Basis weight $\mathrm{lb} / 1000 \mathrm{ft}^{2}$ |  |  |  |  |  |
| 1400. | 39 | 24.72 | 25.80 | 25.10 | 0.21 |

As shown by Table XXII, there is no statistically significant effect due to machine speed for any of the properties considered, with the possible exception of MD Ring Crush. Also, the standard deviations at both machine speeds were significantly higher than the average difference, again indicating that there is no significant difference between the properties for the two speeds.

## handsheet properties - $26 \mathrm{lb} / 1000 \mathrm{ft}^{2}$

This section summarizes the data and predictions for $261 b$ handsheets made from composite samples taken from five locations during the test: hole refiner discharge, blend chest, tickler refiner discharge, headbox and broke chest. Composites were collected at several other locations such as the high density tanks and the white water chest but these were not formed into sheets. Only the heavier handsheet data were studied in detail. The 13 lb data can be found in Appendix IV. These data are discussed in a later section.

The discussion is broken down by property with contrast between positions and time trends forming the basis of the discussion.

## CANADIAN STANDARD FREENESS

CSF should depend on such factors as the freeness of the semi-chemical and OCC furnish from high density storage, refiner power and consistency, fines retention on the wire, broke and saveall recycle and fines losses in stock prep. Freeness profiles, shown in Figures 20 through 24, indicate that with the exception of the headbox predicted values are lower than measured values.

For the simulation model, the predicted freenesses were initialized at the high density storage tanks using a WOODO2 block. The semi-chem freeness was varied for each reel using data from the mill, and freeness changes through the refining system were predicted. Variability in the measured CSF from IPST was greater than the predicted freeness variability, possibly due to measurement error.

Headbox CSF was predicted to be higher than measured CSF and the difference is thought to be due to variations in fines freeness. The model predicted the fines freeness to be in the $200-300 \mathrm{ml}$ range and although no white water freeness data were obtained, the headbox freenesses suggest that the white water freeness was in the 100 ml range. The predicted difference may not be extremely important since most of the fines are not retained in the sheet and the final sheet freeness is more a function of the broke tank or tickler refiner freeness. Thus, the effect of headbox freeness on dry sheet properties may not be as important as stock freeness. However, the headbox CSF does control drainage rates and moisture profiles and should not be glossed over.

Statistical modeling indicates that the three major factors affecting freeness values measured are semi-chem freeness, refiner loading and OCC ratio. On the first day the semi-chem freeness dropped from 722 to 686, but the measured CSF from the primary and tickler refiners decreased by only about 20 ml . This effect is likely due to the "dilution" of the blend stock by the OCC (assuming the OCC CSF is constant). On the first day, the OCC content increased from $18 \%$ to $25 \%$ and primary refiner power increased by $50 \%$ for a brief period.

## Hole Refiner Discharge CSF

The hole refiner CSF is the simplest CSF data to analyze because it is influenced only by the semi-chem furnish and the primary refiner load and consistency. Referring to Figures 20 through 23, the predicted CSF from the hole refiner remained essentially constant for the first two days with the exception of the period when the hole refiner power was increased on reel 2. The predicted variation tracks the measured variation over the first three reels but does not follow the oscillations over the following reels. In particular the large drop in CSF over reels 9 through 12 was not predicted. The measured drop cannot be related to high density CSF since that remains in the 720 ml range. The same relative change was not observed in the mill data.

The measured CSF values shown in Figures 20 through 23 are all IPST measurements. The mill CSF data can be found in Appendix I along with the processing conditions while the IPST CSF data and predictions are shown in Appendix III with the other handsheet data. Comparison of the two sets of measurements shows that the model predictions track the mill data more closely than the IPST data and that there is a much smaller offset between the predicted CSF's and the mill data. The major shift in the predicted CSF and the measured mill and IPST data began on reel 17. But, the magnitude of the CSF drop was not as great as the measured drop. The predicted CSF does track the direction of the change but does not always track the magnitude. The drop is the result of a relatively large increase in primary refiner power over the last 8 reels.

In summary, the model predicts the effect of refining on the semi-chem furnish reasonably well, but the effect of the entering CSF on the discharge CSF is not strong enough. Also, the predicted change in CSF with refiner power was not as strong as observed, indicating that the K-factor model for the refiners may need to be tuned to show greater sensitivity to specific power. The prediction models were validated against the IPST data, and the calculated offset is specific to IPST measurements. The offset against MB data is much smaller (the regression coefficient is closer to l) since the overall CSF levels were set by the level in the high density chest as specified by mill data. Thus, the model predictions also track the mill data more closely than the IPST data.

## Blend Chest CSF

Freeness from the blend chest, as shown in Figure 21, was influenced by the hole refiner freeness, the OCC freeness and the OCC ratio. However, the predicted OCC freeness was assumed to be constant at 316 ml , the "average" of 150 and 650 ml for the hardwood and softwood components of the OCC. Since the OCC freeness was significantly less than the semi-chem freeness the blend chest freeness decreased with increasing OCC content. Generally, the blend chest freeness was approximately 30 ml lower than the hole refiner CSF, as expected for an OCC content of $18 \%$. As OCC content increased to $38 \%$ during day 2 , the CSF decreased to a minimum of about 450. However, the IPST measured freeness from the blend chest was approximately 50
ml lower than the hole refiner, indicating that the OCC CSF may have been lower than the value used in the simulations. Unfortunately, no mill measurements were available from either of the high density chests.

The model predicted a drop in CSF on reel 2, followed by a return to the initial level and a relatively large drop beginning at reel 9 , followed by a gradual return to earlier levels. With the exception of reel 9 , the measurements did not show these trends and fluctuated significantly, especially during the second day.

The blend chest discharge CSF for the third day was influenced primarily by the higher power to the primary refiner, which lowered the hole refiner CSF, and by the higher final OCC content, which also lowered CSF. The predicted and measured data showed very similar responses but the values were offset.

## Tickler Refiner CSF

The tickler refiner discharge CSF was a function of the blend chest discharge CSF, the tickler power, and the tickler feed consistency. Thus, the tickler CSF was expected to drop for reel 2, as predicted by the model and observed by the IPST measurements and the mill measurements. However, a comparison of the "Measured Tickler Refiner CSF" in Appendix I with the IPST measured values in Figure 22 show that the mill measurements corresponded more closely with the predicted values than the IPST values. Since the trends established in the blend chest should be reflected by the tickler discharge for a constant tickler power, the lowest CSF values should have occurred when the blend chest CSF was low and the tickler power was high. The predicted blend chest CSF reached a minimum during reels 9 through 14 and at reel 23 , while the IPST data showed a minimum at reel 23 but did not show the predicted trend. The mill data showed a local shallow minimum for reels 9 through 14 and a sharp drop for reels 18,20 and $23-24$, which did not agree qualitatively with the IPST trends. In addition, the sharp minimum for reel 18 was not predicted by the models.

## Headbox

The headbox CSF, shown in Figure 23, was likely influenced by many process streams but particularly by the fines retention and recycle. The predicted CSF was approximately 60 ml higher than both the IPST and the mill data, indicating that the CSF of the fines in the white water, saveall and broke system was lower than predicted. However, no direct measurement of white water CSF was available.

At times the mill CSF values were as much as 100 ml lower than the predicted values. The predicted low trough for reels 9 through 14 was reflected in the mill data (see Appendix I) but not in the IPST data. Although it was difficult to compare the successive CSF profiles of the IPST measurements, the large "hump" in the IPST data for reels 9 through 14 appeared to persist through the headbox. All data and predictions showed the sharp drop-off in CSF over the last few reels.

## Broke Tank CSF (Figure 24)

The CSF of the broke fibers as shown in Figure 24 should be similar to those of the paper sheet, i.e., a lower fines level and a higher CSF. One would also expect the broke CSF to resemble the tickler discharge CSF, as indicated by a comparison of Figures 22 and 24. The minimum value of broke CSF and tickler discharge CSF was also shown by the predicted profile for broke. Variations in CSF due to refining, while still discernable, were more muted, but could be seen in the data. However, the drop in CSF seen throughout the data at other locations for reels 9 though 14 was not as pronounced for the broke. Mostly, the high value for broke CSF at reel 20 is an outlier since it did not appear in the headbox data.

## Transient effects

The transient behavior of the paper machine system was dominated by the first-order lags of the various storage tanks: high density tanks, blend chest, broke chest and machine chest, and screening and cleaning system. The largest capacity tanks were the high density and broke chests, but these chests were not a problem because the system boundaries began at the chest discharges. With the exception of the broke tank the remaining tanks had very small time constants and did not contribute significantly to transient effects. The estimated time constant for the broke tank was 1 to 2 hours, corresponding to 2 to 3 reels. However, the impact of the broke flow on the transient because of the system depends on the relative contribution of broke to the total flow to the headbox, as shown in Table XXIII. The calculated fiber flows shown in the model are simulated flowrates from the base case (reel l) conditions, and, except for OCC which increased by a factor of 2, the flows remained at these magnitudes throughout the trial.

## Table XXIII Contribution of Broke to Total Fiber Flow Rates

|  | Fiber Flows <br> lb/hr | Relative <br> Contribution |
| :---: | :---: | :---: |
| Semi-chem.. | 37700, | 50 |
| OCC....... | 4250, |  |
| Broke...... | 21400 |  |
| Saveall.... | 22500 | 25 |

Table XXIII indicates that the broke and saveall flows were significant contributors to the total headbox flow and that about half the total flow was raw stock and OCC while the other half was internal recycle from the broke and saveall systems. This represented about $25 \%$ of the total flow; since the broke was returned to the blend chest, both the handsheet data and the machine paper properties could have been influenced by transients due to broke flow. The affect of a single first-order lag on the machine paper properties would be to extend the affect of a process variable such as refining power, freeness change or OCC change beyond the time period the
change. This suggests that handsheet properties from the broke chest onward could have been affected by the characteristics of the broke chest furnish.

However, other evidence suggests that the transient effect may not have been very significant. Comparing Figures 20 and 24, the initial high level of broad maxima in hole refiner discharge CSF followed by a minimum at reel 17 may have resulted in a somewhat broader maximum and a minimum broke CSF value at reel 16 to 17 . Similarly, a second maximum CSF value from the hole refiner over reels 19 and 20 shows up as a very large maximum over reels 19 and 20. This somewhat qualitative correspondence between hole refiner and broke CSF indicates that the transients may be negligible.

## Summary

The predicted CSF values track many of the observed freeness trends, and the reasonably close agreement between the predictions and the mill measurements may indicate that significant inter-laboratory differences exist. Additional modeling error could have been introduced by not accounting for the transient effects of the broke fibers.

## DENSITY

Predicted and measured density profiles are shown in Figures 25 through 29. Density should be influenced by fiber compressibility, which is primarily a function of freeness since other factors (PAT's) remain relatively constant throughout the test. However, the data profiles indicate that density varied erratically for all handsheet data and it was not possible to relate the handsheet density statistically to process conditions. The handsheet density also did not relate to the machine paper density.

However, fundamental principles indicate that density, which is strongly influenced by pressing pressure, should have a strong affect on virtually all other handsheet properties. Thus, the pressure used by the PROPS blocks was varied to approximate the measured density in each case. An hypothesis was set up that, once reasonable agreement with measured densities was obtained, other properties should "fall into line."

Based on CSF data alone, one would expect the density of the hole refiner handsheets to remain relatively constant throughout much of the test, with a gradual increase toward the end of the test as CSF decreased with increased refiner power. However, this response could only be observed in the data by averaging the wide and sudden swings in the densities to see the overall trend. Based on these difficulties, no attempt is made to link the CSF measurements with the density measurements.

An additional factor, sheet forming, may also influence the general trends of the data. When the sheet formation index was varied in the model, the caliper and basis weight variations would result in a variable "effective" handsheet pressing pressure, leading to variable (e.g., lower) density than expected for a 50 psi.
load. Based on these considerations, the press load in the PROPS block was varied for each reel sample and location to approximate the measured density with the hope that the change in density would cause the remaining predicted properties to fall into line with the measurements. Using this approach, the overall fit to the density data was good.

## CALIPER

Caliper profiles are shown in Figures 30 through 34 . Since caliper is related directly to density and basis weight and the basis weight data were used to specify each set of handsheet predictions, the caliper predictions agreed quite well with the measurements.

## TENSILE

The handsheet tensile profiles, shown in Figures 35 through 39, show excellent agreement between predicted and measured data, indicating that the measured data were internally consistent and that the models were able to predict the variable tensiles after fitting the pressing and formation parameter to fit the measured density and burst factor data. The largest disagreement in the results was, as expected, in the broke data where the measured tensiles were generally below the predictions and well below most of the predicted values at other locations. It should be noted that a number of data were missing for the broke tank, possibly influencing the comparisons.

## STRETCH

Profiles of stretch at break are shown in Figures 40 through 44 . There was a persistent offset of at least $50 \%$ to $70 \%$ between the predictions and data at all locations except the broke tank but the stretch profiles did follow the tensile and density profiles, as expected. Generally, the measured values of stretch over the trial were much greater than predicted, possibly due to experimental error. Stretch levels were highest for the headbox and lowest for the hole refiner and broke tank.

## BURST FACTOR

The Burst Factor profiles are shown in Figures 45 through 49. Initially, the predicted and the measured burst values did not agree very well as the predicted values varied frequently with no obvious relationship to freeness changes. However, as discussed above, the density variations were assumed to result from variable formation, and it was reasoned that formation differences would also result in variable strength. Thus, in each case, the burst factor was fit by choosing the appropriate formation level in the PROPS block to obtain reasonably good agreement with the measured values.

It is interesting to note that the predicted average burst level tended to increase from the hole refiner to the blend chest, tickler refiner and headbox, consistent with the notion of improved fiber quality as the fiber approaches the forming section. However, the measured burst for the hole refiner was significantly higher than that of the blend chest which, in turn, was somewhat higher than the tickler refiner, contrary to intuition. Also the broke levels were even lower than the tickler discharge, contrary to the expected effect of freeness differences between the two tanks. These unexpected measured values could possibly be the result of unexpected changes in the fines contact of the furnish.

## COMPRESSIVE PROPERTIES

## Ring Crush

Profiles of Ring Crush, shown in Figures 50 through 54, indicate a high variability over the trial with no significant trends. There was a large offset between the predicted and measured levels which was relatively constant at each location. The model's predicted values of ring crush showed little change from the hole refiner to the tickler refiner discharge although the measured data did decrease, contrary to expectations. As expected, the headbox values are higher and the broke chest values lower.

The predictive model used in MAPPS indicated that ring crush will depend on directional moduli as well as caliper. However, the modulus was not measured for the handsheets so there was no independent measurement to decouple caliper and moduli.

## Concora

Profiles of the measured Concora values, Figures 55 through 59, indicate that there was an oscillatory variation, particularly at the hole refiner, and it is unlikely that this variation could be real. Therefore, interpretation of the concora data was based on the average trending of the data. Using this approach, it can be concluded that there was very little change over the 24 test reels, in agreement with the average predicted trend. However, there was a constant offset of about 10 to 12 lb between measured and predicted values, with the predictions consistently higher than the IPST measurements. The mill concora data were consistently higher than the IPST data, but these data were not included in the statistical analysis so no direct comparisons could be made.

The models predict that concora values were about the same for the first three locations and then increased at the headbox and decreased at the broke chest. However, the predicted broke values were generally higher than the concora from the tickler refiner while the measured values were consistently lower.

In summary, the absence of a trend in compressive properties was predicted by the models. In theory, the major effect of furnish composition on compressive properties was expected to be a function of CSF. However, this effect was masked by
significant variations in handsheet density and formation levels which affect bonding. Generally, for the range of density levels used, the predicted compressive property levels were in good agreement with literature and other IPST data of Whitsitt on which the models were based. Thus, it may be concluded that the offset between predictions and IPST data can be applied to the mill lab data and historical data from Whitsitt to adjust the model parameters.

The handsheet data do confirm one result of the machine paper property analysis, namely, that OCC content has no significant affect on compressive properties. Refining was also predicted to have only a very slight affect for similar reasons. The primary effect of refining, a decrease of CSF and an increase in surface area, increases density and, for constant basis weight, decreases caliper and increases modulus.

As discussed above, the decreased caliper tended to cancel the increase in modulus and no net affect on compressive properties was expected. However, the models did show that fiber modulus could be affected by refining and that changes in fiber modulus could bring about changes in sheet modulus without corresponding changes in sheet caliper. This could result in some affect on compressive properties. For similar reasons, the models indicate that different species would show considerably different compressive strength even at the same freeness and density.

## Porosity

Gurley porosity profiles are shown in Figures 60 through 64 . The models indicate that porosity profiles should vary directly with density profiles since Gurley porosity is inversely related to porosity and porosity should be inversely related to density. However, the measured porosity data were highly variable and no conclusions could be drawn from the individual values. It is interesting that many of the local variations in porosity, particularly at the blend chest, are predicted but with lower amplitude. The high variability of the measured porosity is also indicative of the assumption that the handsheet formation index varied significantly from sample to sample.

Porosity predictions at the hole refiner tended to pass through the average of the data values. The blend chest and other locations showed an offset between the porosity predictions and measured data with the greatest offset occurring at the headbox. The porosity model depends primarily on freeness and density. The headbox furnish was dominated by fines, resulting in higher predictions of the headbox freeness, which, because porosity is a function of freeness and density, led to the higher predicted porosity values.
model discrepancies • problem areas
Large deviations in predicted versus neasured property behavi or occurred when the cal enderi ing effects were nodel ed. In particular, the predi cted effect of cal ender I oading on tensile strength and burst was hi gher than neasured val ues. This is due to the fact that the nodels predicted that, under the mild cal endering conditions used at the nill, cal endering increased both bulk density and bond density, resulting in increased nodul us and tensile strength. However, there is a large body of evidence linking nodul us to strength and it was expected that the strength properties nould parallel the stiffnesses. Thus, the apparent decoupling bet neen densification and tensile strength observed in the neasured data will require sone review of the nodel s.

A second problem area was related to densification in the press section where the nodel $s$ predi cted much higher level $s$ of fiber-fiber contact on one side of the sheet than on the other. These differences were a result of the gradi ent in fiber length through the thi ckness of the nat which caused the freeness and fi ber surface area to vary. The sensitivity of the fiber contact area devel oped during pressing to CSF was too great, and these nodel s must be revi ewed and nodified to correct this problem

## VALIDATION

Mbdel validity is based on the "goodness of fit" between the predicted and neasured val ues for each property shown in Tabl es XXIV and XXV (See Appendi $\mathrm{X} V$ ). The nodel used for the goodness of fit analysis has the following form

$$
\text { neasured property }=C \text { * predi cted property }
$$

To performthe intercept, the nodel was forced to zero so that "perfect fit" nould be one for which correction coefficient, $C$, is 1 and the $R$-squared error val ue is 1.0. The correction coefficient is a neasure of the error in the nodel in predicting the nean val ue of the data. Based on the R-squared criteria, the goodness of fit for nost of the properties was excellent since the correction coefficient and R-Squared statistic were close to 1 . Corrections for machine paper properties are generally closer to one than for handsheets. The general variability of the handsheet data was the likel $y$ cause of the higher correction factors. For exanple, the correction for handsheet concora was 0.766 while that for machine paper concora is 0.92 i ndi cating that handsheet concora on the average predi cted hi gher val ues $24 \%$ of the tine while machine paper concora predicted higher val ues only $8 \%$ of the tine.

It should be noted that the $\mathbf{R}$-squared val ues onl y appl y to the corrected nodel s and that those for the uncorrected nodels nould be expected to be sonewhat lower.

Table XXIV: GOODNESS OF FIT

| Variable | $\mathrm{R}^{2}$ | Coefficient | F | Mean | CV | $\begin{aligned} & \text { T for } \\ & \text { HO } \end{aligned}$ | Root MSE |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| CSF, ml. | 0.984 | 1.0711 | 6745 | 503 | 12.8 | 82.13 | 64.5 |
| Breaking Length, km.. | 0.959 | 0.936 | 2392 | 3.64 | 20.9 | 48.91 | 0.76 |

| Ring Crush, lb | 0.939 | 1.62 | 1685 | 53.5 | 25.14 | 41.05 | 13.5 |
| Burst Factor | 0.968 | 1.01 | 3377 | 23.0 | 18.06 | 58.12 | 4.15 |
| Porosity. | 0.647 | 1.033 | 200 | 16.0 | 75.2 | 14.15 | 12.0 |
| Density, g/cc. | 0.992 | 0.982 | 13608 | 0.411 | 9.08 | 116.65 | 0.037 |

Table XXV Goodness of Fit

Statistically, the R-Squared criteria overestimates the goodness of fit but the over estimate is not significant when the correction factors approach 1 . Since the correction factors represent the average error in the predictions, a second criteria for model validity is that the average error of the model should fall within the confidence limits of measurement error for each property (See Tables XXVI \& XXVII).

Table XXVI: Goodness of Fit Based on Measurement Error

| Goodness of Fit - Handsheet Data |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Table XXVII Goodness of Fit Based on Measurement Error

| Machine Paper |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Goodness of Fit Based on Measurement Error |  |  |  |  |  |
| Property | Correl Coefficient | Avg Error \% | Mean | Measure <br> Std Dev | $\begin{gathered} \text { Confid Band } \\ 90 \% \\ \text { Absol \% } \end{gathered}$ |
| MD Tensile, km. | 0.994 | 1 | 5.98 | 0.39 | 13 |
| CD Tensile, km....... | 1.01 | 1 | 2.54 | 0.19 | 15 |
| Burst Factor. | 0.96 | 4 | 29.0 | 2.3 | 16 |
| Density, g/cc. | 0.96 | 4 | 0.589 | - | - |
| Concora, lb... | 0.92 | 8 | 54.53 | 3.6 | 13.2 |
| CD Ring Crush........ | 1.45 | 45 | 32.5 | 6.4 | 39.4 |
| MD STFI. | 1.233 | 23 | 22.7 | 3.8 | 33 |
| CD STFI. | 1.173 | 17 | 14.5 | 3.2 | 44 |
| MD Modulus, GPa | 0.948 | 5 | 4.33 | 0.31 | 14.3 |
| MD Stretch, \% | 0.915 | 8.5 | 1.637 | 0.22 | 27 |

The confidence bands for each variable are based on twice the standard deviation divided by the mean and expressed as a percent. When the confidence bands are compared with the percent error of the model based on the correction factors, all the models except CD Ring Crush are within measurement error. When the high level of correlation for the corrected model is taken into account, it could be stated that the model is not biased and is therefore also valid as corrected. Thus, a second validation criteria is that the model predictions are valid within measurement error.

Correction factors outside of the measurement error do not necessarily indicate an invalid model. In some cases, the corrections may also include the effects of variability of the laboratory testing procedures. In particular, differences between mill and IPST compressive strength measurements such as STFI and concora indicate that an interlaboratory study may be desirable.

Statistically, it may be concluded that, if the correction is a single factor and the resulting corrected values agree very well with the measurements as measured by R-squared, the model is a useful tool and therefore valid for this grade.

## Handsheet Properties - $13 \mathrm{lb} / 1000 \mathrm{ft}^{2}$

The data on the lighter weight handsheets were used primarily to study the zero span tensile strength variations during the trial; for individual data see Appendix IV. The model did not predict a significant variation in zero span tensile. Both the OCC and semi-chem fiber zero-span tensile were initialized with a breaking length of 10 km and the final predicted zero-span values were about 9.5 km as compared to an average of 9.05 km for all 13 lb handsheets measured. The statistics on the 13 lb sheets are summarized in Table XXVIII.

Table XXVIII: Light Weight Handsheet Properties

| Property | Minimum | Maximum | Mean | Std Dev |
| :---: | :---: | :---: | :---: | :---: |
| Basis Weight. | 50.7 | 81.5 | 65.0 | 3.27 |
| Caliper, mils. | 6.05 | 13.7 | 8.45 | 1.42 |
| Density, g/cc. | 0.185 | 0.397 | 0.313 | 0.05 |
| Tensile, km . | 1.51 | 4.99 | 3.55 | 0.71 |
| Burst Factor | 12.5 | 26.4 | 19.7 | 3.15 |
| Stretch, \%. | 0.61 | 2.30 | 1.47 | 0.34 |
| Gurley Porosity. | 1.45 | 18.0 | 4.75 | 3.43 |
| Zero Span Tensile, km. | 6.74 | 12.00 | 9.05 | 0.90 |
| Moisture, \%. | 4.92 | 7.33 | 6.12 | 0.51 |

The examination of the measured zero span data for each location indicates that the zero span tensile did not change significantly throughout the process or with time during the trial. Some handsheet data from the mill were available to compare with the data from IPST and the model predictions. These data, which represent a single set of beating curves from 280 to 606 ml CSF, are summarized in Table XXIX.

The 13 lb handsheet had lower densities than the 26 lb sheets. The mean density of the light weight sheets was 0.313 as compared to a mean value of 0.411 for the 26 lb handsheets. Over most of the range in basis weight, density does not depend on basis weight. However, for low basis weight, density apparently increases with basis weight. One possible explanation for the higher density of the 13 lb is that the formation was more variable and could have resulted in a variation in caliper causing a nonuniform application of pressing pressure and nonuniform densification. Both the nonuniformity in density and formation itself would have contributed to lower tensile properties for the lower basis weight sheets.

Gurley porosity of the light weight handsheets (4.75) was also considerably lower than the 26 lb handsheet values of 16 , indicating that the light weight handsheets had considerably higher porosity. The porosity differences were in agreement with the observed density differences.

It is interesting to note that the mean tensile strength (breaking length) of the light weight sheets, 3.55 km , was not significantly lower than the mean of the 26 lb sheets, 3.64 km , while the burst factor of 19.7 for the 13 lb handsheets was significantly lower than the value of 23.0 for the 26 lb handsheets. The similar tensile strength values indicate that formation of the 13 lb handsheet was equal or superior to that of the 26 lb handsheets. Theoretically, the more uniform formation (higher formation index) compensates for the lower density resulting in about the same tensile strength (other things being equal).

The models would have been able to predict the light weight handsheet data although this work was not done. It would have been necessary to assume a lower effective pressing pressure for the light weight sheets to fit the density and a corresponding higher formation index to fit the tensile or burst data.

## Interlaboratory Differences

A limited set of property data were provided by the mill. The properties of interest were concora, STFI and freeness at the primary discharge, tickler discharge and headbox discharge. The Concora and Headbox CSF are summarized in Table XXX along with the IPST data and model predictions. These comparisons indicate that the model predictions tend to follow the mill concora and CSF data rather than the IPST data. Said another way, the mean values of the model prediction for each of these variables was closer to the mean of the mill data than to the mean of the IPST data. However, it was shown above that the models "tracked" the IPST data quite well with an offset. The concora model is based on data of whitsitt obtained from numerous laboratory and mill sources and the differences shown in Table XXX indicate that the concora testing procedure at IPST may have been different.

The CSF data are indicative of the large variations that can occur with CSF measurements. The differences between the model predictions of headbox CSF were the largest of any location as a result of the high fines content of the predicted headbox stock fines as with Concora the predicted values were closer to the mill CSF values than to the IPST values.

Analysis of the mill beater data (See Table XXIX) also indicates laboratory differences; for instance, the zero span values of the beaten pulps were 7.3 km , as compared to 9.05 km measured by IPST and 9.5 km predicted by the model. The mean CSF of the handsheets tested at IPST was about 500 ml , corresponding to the column at a beating time of 8 minutes where the freeness was 493. At this level of CSF the mill handsheet density was $0.527 \mathrm{~g} / \mathrm{cc}$ compared to $0.411 \mathrm{~g} / \mathrm{cc}$ for the IPST handsheets. The breaking lengths were similar, however, with the mill breaking length of 3.9 km being only slightly higher than the IPST mean breaking length of 3.64 km . The mill handsheet data at 500 ml CSF and mean IPST handsheet data at 493 m1 CSF.

Table XXIX: Mill Handsheet Data

|  | Beating Time, minutes |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
|  | 0 | 8 | 13 | 18 |
| CSF, ml........ | 606 | 493 | 407 | 280 |
| Basis Weight.... | 28.24 | 28.31 | 28.29 | 28.49 |
| Density, g/cc... | 0.475 | 0.527 | 0.549 | 0.582 |
| Tensile, km..... | 2.1 | 3.9 | 4.7 | 5.1 |
| Burst Factor.... | 14.0 | 23.1 | 28.6 | 32.7 |
| Stretch, \%...... | 1.3 | 2.8 | 3.3 | 3.6 |
| Gurley Porosity. | 1.1 | 4.1 | 11.7 | 44.6 |
| Concora, lb..... | 27.8 | 49.0 | 66.2 | 73.9 |
| Ring Crush, ib.. | 33.9 | 49.2 | 61.1 | 65.1 |
| Zero Span, km... | 5.0 | 7.3 | 7.3 | 7.3 |
| STFI, lb./in.... | 12.2 | 16.7 | 19.0 | 20.9 |

It may be concluded from these data that the comparable breaking length for the two sets of handsheets is a result of the higher density for the mill data, which offsets the lower zero span tensile. The burst factors of the two handsheet were also very close, indicating that the tensile strengths and compressive properties were comparable. The slightly lower mill compressive properties were likely a result of the lower caliper of the mill sheets at the same basis weight due to the higher sheet. Thus, the compressive properties would be expected to be comparable because, as mentioned above, the compressive property models show that there is a trade-off between caliper and modulus.

## Correlative Analysis of Machine Property Data

A correlative analysis of the machine property data indicates that, with minor exceptions, machine paper properties data were not significantly affected by any single independent variable. Correlative models of all properties were used to test the importance of both independent and dependent variables on properties such as density, breaking length, burst, stiffnesses and compressive properties. For example, concora was tested for dependence on stiffness and caliper, reported by the literature to be significant, as well as density, stack loading, machine speed, press loading, OCC, etc. Dependent property variables such as burst were tested for correlation with breaking lengths and stretch as well as machine conditions and refining. All the models had a very poor overall fit to the data but the models did identify one or two variables which had some influence on the correlated property. The results of this analysis are summarized in Table XXXII.

Table XXXII: Correlative Analysis

| Dependent Variables | Significant Independent Variables | $\begin{aligned} & \text { Type } \\ & \text { I SS } \end{aligned}$ | F | Total SS |
| :---: | :---: | :---: | :---: | :---: |
| MD Tensile.... | Density. <br> Pullstack on/off.... <br> Machine Speed......... | $\begin{aligned} & 0.47 \\ & 1.55 \\ & 3.72 \end{aligned}$ | $\begin{aligned} & 4.4 \\ & 24 \\ & 58 \end{aligned}$ | 12.9 |
| MD Modulus..... | $\begin{aligned} & \text { Density } \quad \text {. . . . . . . . . . . } \\ & \text { Density } \end{aligned}$ | $\begin{aligned} & 2.97 \\ & 2.50 \end{aligned}$ | $\begin{aligned} & 58 \\ & 49 \end{aligned}$ | 11.19 |
| Burst Factor.. | MD $\times$ CD Tensile. | 146 | - | 275 |
| Density....... | Pullstack on/off..... High Density CSF..... OCC ratio. | $\begin{aligned} & 0.047 \\ & 0.013 \\ & 0.0087 \end{aligned}$ | $\begin{aligned} & 131 \\ & 19 \\ & 25 \end{aligned}$ | 0.108 |
| CD Ring Crush. | Machine Speed........ | 231 | - | 3121 |
| Concora. | Pull stack on/off.... | 88.5 | 12 | 879 |

From the table, it can be seen that density was most strongly affected by calender loading which was confirmed by the models and the measured data. Density also showed a lower dependence on freeness and OCC ratio, but the contribution to the total sum of squares value of 0.108 was only 0.013 and 0.0087 for CSF and OCC ratio, respectively.

MD Modulus could be related only to sheet density or various powers of density. The density relationship is fundamentally sound and was confirmed by the correlative analysis. However, the contribution of density was only $50 \%$ of the total variation in the data indicating that other factors must contribute to the variability. The predictive model used by MAPPS assumes that the tensile and modulus ratio was relatively constant throughout the test and was confirmed by the measured data. Thus, it is unlikely that variable stretch and/or shrinkage resulted in MD/CD variations which would have influenced modulus.

Burst Factor was most strongly related to the product of the MD and CD tensile strength although the square root function used in the model would have given a stronger correlation. Stretch was not found to contribute, possibly due to the form of the model.

MD tensile strength was most strongly dependent on machine speed with a small but significant dependence on calender stack loading and density. All of these effects could be expected based on fundamental modelling considerations. Machine speed is a factor because it influences the $M D / C D$ tensile ratio. Stack loading can affect tensile through bonding/debonding behavior or through stress relaxation which also affects MD/CD tensile ratio. Density affects tensile because it is a measure of the degree of bond formation or breaking occurring under load. However, the sum of these three terms was still not sufficient to provide a good predictive model for MD breaking length.

It is interesting to note that concora could not be related to ring crush, and STFI, or elastic moduli even though a fundamental relationship should exist. Ring Crush appeared to be dependent on machine speed, indicating that $M D / C D$ tensile ratio may influence ring crush variations.

## CONCLUSIONS - Validation Study

Based on the two validation criteria and estimates of measurement error, the model system appears to be valid for corrugating medium. Correction factors for some properties may need to be applied to some of the property predictions. Two areas in the models will require modification. A follow-up calendering test is recommended to reconcile and confirm the conclusions of the effects of calender load.

There is some evidence of transient effects when looking at the handsheet CSF and machine paper data but these effects could not be separated from the overall variations in the data. Property variation with time appeared to be a response to several causes:

## Performance Attribute Validation Study On Corrugating Medium

1. property measurement error (no real cycling)
2. CD variability
3. semi-chem CSF and other inputs to the system (real effect)
4. unmeasured variables which changed
5. measured and controlled test variables
6. holdups in tanks (first-order lags) which propagated through the system diluting certain effects and propagating others

The high level of the correlations leads to the following conclusions:

1. The data were highly consistent internally.
2. The major factors affecting properties were accounted for in the models.
3. Many factors which were held constant or calculated to be constant, e.g., machine paper formation, were indeed approximately constant.
4. Those factors which did change during the trials were most probably the major factors affecting properties.
5. The fundamental basis for predicting property development appears to be reasonably well understood.
6. The properties depend on each other in a hierarchical structure, i.e., density, tensile, and elastic properties, derived properties such as burst factor (and tear), compressive properties such as STFI and flat crush and, finally, highly derived properties such as ring crush and concora.
7. The predictable response of the handsheet and machine paper properties to process changes indicates that the overall model structure and concepts are consistent.
8. Areas of weakness appear to be the exact sensitivity of the contact development with pressing and the relationship between density, bond density, modulus and strength.
9. It appears that modulus is a function of density rather than bonding per se. This conclusion seems reasonable because the elastic stiffnesses can be measured as the transmission of waves (ultrasonic) through the sheet which should depend on the contacts between fibers rather than the bonds.
10. Tensile properties which depend on bond failure should relate directly to bond density and strength, indicating that light calendering of this grade does not affect the bonding in the sheet but does affect the contacts and density of the sheet.

Overall, the models performed well from a statistical point of view -- the only objective means of determining model validity. A transient simulation model with CSTR's and first-order lags in the system would have been helpful. Such a system will be developed to use for future validation work.

Handsheet formation and pressing should be more consistently controlled in future work. The handsheet data were highly variable, apparently due to variable formation and pressing pressure. Thus, variability of the data limited their utility in the validation. There were also interlaboratory differences which should be studied further.

Future validation studies should include the modules necessary to predict $C D$ variations through the paper machine, wet press, drier and calender sections for comparison with the measured CD property data.

The effects of OCC, refining, pressing and machine speed were surprisingly small for this grade. These effects were quantified in the following sensitivity study by using the simulation model to eliminate transient effects and interactions between variables.

## Model Modifications

Based on the results of this analysis, the following model changes will be made:

1. Reduce the CSF dependence of the wet compressibility model.
2. Change the modulus models so they depend on bulk density rather than bond density.
3. Change the Gurley porosity to depend on surface density rather than bulk density.
4. Increase the sensitivity of CSF to specific power for lower yield furnishes in the refiner models.

## SENSITIVITY ANALYSIS

The sensitivity analysis was performed using the model with Reel l conditions as the basis for determining the expected affect of four major test variables on end-user performance. By changing only one variable at a time using the model, it was possible to obtain unambiguous estimates of the decoupled sensitivity of each property to a specific variable. The four parameters were varied, as follows: (1) OCC content - $18 \%$ to $38 \%$, (2) hole \& tickler refiner loads - minimum to maximum values, (3) press load - minimum to maximum values, and (4) calender stack - loaded or unloaded. The variable conditions are summarized in Table XXXIII.

The sensitivity study was done without changing any of the models. In light of the findings of the validation study, the sensitivity coefficients for the effect of calendering on tensile properties were assumed to be zero even though the current models predicted a drop in tensile, burst and stretch. The sensitivity coefficients for the contact areas and bond area PAT's, $\mathrm{S}_{\mathrm{b} 1}, \mathrm{~S}_{\mathrm{b} 2}$ and $\mathrm{S}_{\mathrm{a}}$ may also change after the wet press densification model is modified.

## Interactions between Pressing, Drying and Calendering

One additional factor which influences the effect of press load on sheet properties is the final sheet moisture. In the cases above, the stream flows were adjusted to achieve a constant outlet dryness. If the steam flows had not been varied, sheet moisture levels: would have been reduced to $90 \%$ for the low press load case and would have increased to $97 \%$ for the high press load case. The higher moisture would have

Performance Attribute Validation Study On Corrugating Medium
resulted in a slight improvement in predicted tensile properties from calendering while the lower moisture predicted reduced tensile strength due to calendering.

Table XXXVI and XXXVII show the effect of dryer steam flow in combination with press load on final sheet moisture and machine paper properties from the calender, respectively. The modeling results indicate that the press loading level interacts with the calendering causing a bonding or debonding effect depending on the sheet moisture and roll temperature in the calender nip. This effect is independent of the basic consolidation effect of the press on the sheet in the wet state.

Table XXXVI: Press Load Sensitivity - Interaction with Calendering

## CONCLUSIONS - Sensitivity Study

The sensitivity study showed that OCC had little effect on compressive properties but did increase some tensile properties slightly. Refining had a strong effect on CSF, improving the sheet density. However, the models predicted a reduction in fiber length (coincident with the CSF drop) and fiber tensile strength tending to reduce tensile properties such as breaking length and burst factor.

Third nip press load had little affect on properties, provided the sheet moisture entering the calender was constant. However, this effect is influenced by the debonding of the sheet predicted by the current model. Since this debonding did not occur, the interactions between the press load, moisture and calendering were probably not real for the low loading for this grade.

The calender stack, even at low loading, increased the sheet density and sheet stiffnesses but there was only a negligible affect on compressive properties. The affect on tensile properties was also negligible.

## ACKNOWLEDGEMENTS

The author would like to thank the member companies of the Institute of Paper Science and Technology for their support of this project. Special thanks go to Joe Cook and all those at MacMillan-Bloedel, Inc. for their cooperation in all phases of the mill trial. Thanks also to J. D. Rushton and R. Ellis of IPST for their invaluable assistance in planning and design of the trial, design of the sampling plan and in sample collection and data interpretation.

Table XXV Goodness of Fit

Statistically, the R-Squared criteria overestimates the goodness of fit but the over estimate is not significant when the correction factors approach l. Since the correction factors represent the average error in the predictions, a second criteria for model validity is that the average error of the model should fall within the confidence limits of measurement error for each property (See Tables XXVI \& XXVII).

Table XXVI: Goodness of Fit Based on Measurement Error

| MD Tensile, km. | 0.994 | 1 | 5.98 | 0.39 | 13 |
| CD Tensile, km. | 1.01 | 1 | 2.54 | 0.19 | 15 |
| Burst Factor. | 0.96 | 4 | 29.0 | 2.3 | 16 |
| Density, g/cc. | 0.96 | 4 | 0.589 | - | - |
| Concora, lb.. | 0.92 | 8 | 54.53 | 3.6 | 13.2 |
| CD Ring Crush........ | 1.45 | 45 | 32.5 | 6.4 | 39.4 |
| MD STFI................ | 1.233 | 23 | 22.7 | 3.8 | 33 |
| CD STFI............... | 1.173 | 17 | 14.5 | 3.2 | 44 |
| MD Modulus, GPa...... | 0.948 | 5 | 4.33 | 0.31 | 14.3 |
| MD Stretch, \%. | 0.915 | 8.5 | 1.637 | 0.22 | 27 |

The confidence bands for each variable are based on twice the standard deviation divided by the mean and expressed as a percent. When the confidence bands are compared with the percent error of the model based on the correction factors, all the models except CD Ring Crush are within measurement error. When the high level of correlation for the corrected model is taken into account, it could be stated that the model is not biased and is therefore also valid as corrected. Thus, a second validation criteria is that the model predictions are valid within measurement error.

Correction factors outside of the measurement error do not necessarily indicate an invalid model. In some cases, the corrections may also include the effects of variability of the laboratory testing procedures. In particular, differences between mill and IPST compressive strength measurements such as STFI and concora indicate that an interlaboratory study may be desirable.

Statistically, it may be concluded that, if the correction is a single factor and the resulting corrected values agree very well with the measurements as measured by R-squared, the model is a useful tool and therefore valid for this grade.

## Handsheet Properties - $13 \mathrm{lb} / 1000 \mathrm{ft}^{2}$

The data on the lighter weight handsheets were used primarily to study the zero span tensile strength variations during the trial; for individual data see Appendix IV. The model did not predict a significant variation in zero span tensile. Both the OCC and semi-chem fiber zero-span tensile were initialized with a breaking length of 10 km and the final predicted zero-span values were about 9.5 km as compared to an average of 9.05 km for all 13 lb handsheets measured. The statistics on the 13 lb sheets are summarized in Table XXVIII.

Table XXVIII: Light Weight Handsheet Properties

| Property | Minimum | Maximum | Mean | Std Dev |
| :---: | :---: | :---: | :---: | :---: |
| Basis Weight | 50.7 | 81.5 | 65.0 | 3.27 |
| Caliper, mils. | 6.05 | 13.7 | 8.45 | 1.42 |
| Density, g/cc | 0.185 | 0.397 | 0.313 | 0.05 |
| Tensile, km. | 1.51 | 4.99 | 3.55 | 0.71 |
| Burst Factor | 12.5 | 26.4 | 19.7 | 3.15 |
| Stretch, \%. | 0.61 | 2.30 | 1.47 | 0.34 |
| Gurley Porosity | 1.45 | 18.0 | 4.75 | 3.43 |
| Zero Span Tensile, km.. | 6.74 | 12.00 | 9.05 | 0.90 |
| Moisture, \%. | 4.92 | 7.33 | 6.12 | 0.51 |

The examination of the measured zero span data for each location indicates that the zero span tensile did not change significantly throughout the process or with time during the trial. Some handsheet data from the mill were available to compare with the data from IPST and the model predictions. These data, which represent a single set of beating curves from 280 to 606 ml CSF, are summarized in Table XXIX.

The 13 lb handsheet had lower densities than the 26 lb sheets. The mean density of the light weight sheets was 0.313 as compared to a mean value of 0.411 for the 26 lb handsheets. Over most of the range in basis weight, density does not depend on basis weight. However, for low basis weight, density apparently increases with basis weight. One possible explanation for the higher density of the 13 lb is that the formation was more variable and could have resulted in a variation in caliper causing a nonuniform application of pressing pressure and nonuniform densification. Both the nonuniformity in density and formation itself would have contributed to lower tensile properties for the lower basis weight sheets.

Gurley porosity of the light weight handsheets (4.75) was also considerably lower than the 26 lb handsheet values of 16, indicating that the light weight handsheets had considerably higher porosity. The porosity differences were in agreement with the observed density differences.

It is interesting to note that the mean tensile strength (breaking length) of the light weight sheets, 3.55 km , was not significantly lower than the mean of the 26 lb sheets, 3.64 km , while the burst factor of 19.7 for the 13 lb handsheets was significantly lower than the value of 23.0 for the 26 lb handsheets. The similar tensile strength values indicate that formation of the 13 lb handsheet was equal or superior to that of the 26 lb handsheets. Theoretically, the more uniform formation (higher formation index) compensates for the lower density resulting in about the same tensile strength (other things being equal).

The models would have been able to predict the light weight handsheet data although this work was not done. It would have been necessary to assume a lower effective pressing pressure for the light weight sheets to fit the density and a corresponding higher formation index to fit the tensile or burst data.

## Interlaboratory Differences

A limited set of property data were provided by the mill. The properties of interest were concora, STFI and freeness at the primary discharge, tickler discharge and headbox discharge. The Concora and Headbox CSF are summarized in Table XXX along with the IPST data and model predictions. These comparisons indicate that the model predictions tend to follow the mill concora and CSF data rather than the IPST data. Said another way, the mean values of the model prediction for each of these variables was closer to the mean of the mill data than to the mean of the IPST data. However, it was shown above that the models "tracked" the IPST data quite well with an offset. The concora model is based on data of whitsitt obtained from numerous laboratory and mill sources and the differences shown in Table XXX indicate that the concora testing procedure at IPST may have been different.

The CSF data are indicative of the large variations that can occur with CSF measurements. The differences between the model predictions of headbox CSF were the largest of any location as a result of the high fines content of the predicted headbox stock fines as with Concora the predicted values were closer to the mill CSF values than to the IPST values.

Analysis of the mill beater data (See Table XXIX) also indicates laboratory differences; for instance, the zero span values of the beaten pulps were 7.3 km , as compared to 9.05 km measured by IPST and 9.5 km predicted by the model. The mean CSF of the handsheets tested at IPST was about 500 ml , corresponding to the column at a beating time of 8 minutes where the freeness was 493 . At this level of CSF the mill handsheet density was $0.527 \mathrm{~g} / \mathrm{cc}$ compared to $0.411 \mathrm{~g} / \mathrm{cc}$ for the IPST handsheets. The breaking lengths were similar, however, with the mill breaking length of 3.9 km being only slightly higher than the IPST mean breaking length of 3.64 km . The mill handsheet data at 500 ml CSF and mean IPST handsheet data at 493 ml CSF.

Table XXIX: Mill Handsheet Data

|  | Beating Time, minutes |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
|  | 0 | 8 | 13 | 18 |

| Tensile, km..... | 2.1 | 3.9 | 4.7 | 5.1 |
| Burst Factor.... | 14.0 | 23.1 | 28.6 | 32.7 |
| Stretch, \%..... | 1.3 | 2.8 | 3.3 | 3.6 |
| Gurley Porosity. | 1.1 | 4.1 | 11.7 | 44.6 |
| Concora, lb..... | 27.8 | 49.0 | 66.2 | 73.9 |
| Ring Crush, 1b.. | 33.9 | 49.2 | 61.1 | 65.1 |
| Zero Span, km... | 5.0 | 7.3 | 7.3 | 7.3 |
| STFI, lb./in.... | 12.2 | 16.7 | 19.0 | 20.9 |

It may be concluded from these data that the comparable breaking length for the two sets of handsheets is a result of the higher density for the mill data, which offsets the lower zero span tensile. The burst factors of the two handsheet were also very close, indicating that the tensile strengths and compressive properties were comparable. The slightly lower mill compressive properties were likely a result of the lower caliper of the mill sheets at the same basis weight due to the higher sheet. Thus, the compressive properties would be expected to be comparable because, as mentioned above, the compressive property models show that there is a trade-off between caliper and modulus.

## Performance Attribute Validation Study On Corrugating Medium

MD Modulus could be related only to sheet density or various powers of density. The density relationship is fundamentally sound and was confirmed by the correlative analysis. However, the contribution of density was only $50 \%$ of the total variation in the data indicating that other factors must contribute to the variability. The predictive model used by MAPPS assumes that the tensile and modulus ratio was relatively constant throughout the test and was confirmed by the measured data. Thus, it is unlikely that variable stretch and/or shrinkage resulted in MD/CD variations which would have influenced modulus.

Burst Factor was most strongly related to the product of the MD and CD tensile strength although the square root function used in the model would have given a stronger correlation. Stretch was not found to contribute, possibly due to the form of the mode1.

MD tensile strength was most strongly dependent on machine speed with a small but significant dependence on calender stack loading and density. All of these effects could be expected based on fundamental modelling considerations. Machine speed is a factor because it influences the $M D / C D$ tensile ratio. Stack loading can affect tensile through bonding/debonding behavior or through stress relaxation which also affects MD/CD tensile ratio. Density affects tensile because it is a measure of the degree of bond formation or breaking occurring under load. However, the sum of these three terms was still not sufficient to provide a good predictive model for MD breaking length.

It is interesting to note that concora could not be related to ring crush, and STFI, or elastic moduli even though a fundamental relationship should exist. Ring Crush appeared to be dependent on machine speed, indicating that MD/CD tensile ratio may influence ring crush variations.

## CONCLUSIONS - Validation Study

Based on the two validation criteria and estimates of measurement error, the model system appears to be valid for corrugating medium. Correction factors for some properties may need to be applied to some of the property predictions. Two areas in the models will require modification. A follow-up calendering test is recommended to reconcile and confirm the conclusions of the effects of calender load.

There is some evidence of transient effects when looking at the handsheet CSF and machine paper data but these effects could not be separated from the overall variations in the data. Property variation with time appeared to be a response to several causes:

1. property measurement error (no real cycling)
2. CD variability
3. semi-chem CSF and other inputs to the system (real effect)
4. unmeasured variables which changed
5. measured and controlled test variables
6. holdups in tanks (first-order lags) which propagated through the system diluting certain effects and propagating others

The high level of the correlations leads to the following conclusions:

1. The data were highly consistent internally.
2. The major factors affecting properties were accounted for in the models.
3. Many factors which were held constant or calculated to be constant, e.g., machine paper formation, were indeed approximately constant.
4. Those factors which did change during the trials were most probably the major factors affecting properties.
5. The fundamental basis for predicting property development appears to be reasonably well understood.
6. The properties depend on each other in a hierarchical structure, i.e., density, tensile, and elastic properties, derived properties such as burst factor (and tear), compressive properties such as STFI and flat crush and, finally, highly derived properties such as ring crush and concora.
7. The predictable response of the handsheet and machine paper properties to process changes indicates that the overall model structure and concepts are consistent.
8. Areas of weakness appear to be the exact sensitivity of the contact development with pressing and the relationship between density, bond density, modulus and strength.
9. It appears that modulus is a function of density rather than bonding per se. This conclusion seems reasonable because the elastic stiffnesses can be measured as the transmission of waves (ultrasonic) through the sheet which should depend on the contacts between fibers rather than the bonds.
10. Tensile properties which depend on bond failure should relate directly to bond density and strength, indicating that light calendering of this grade does not affect the bonding in the sheet but does affect the contacts and density of the sheet.

Overall, the models performed well from a statistical point of view -- the only objective means of determining model validity. A transient simulation model with CSTR's and first-order lags in the system would have been helpful. Such a system will be developed to use for future validation work.

Handsheet formation and pressing should be more consistently controlled in future work. The handsheet data were highly variable, apparently due to variable formation and pressing pressure. Thus, variability of the data limited their utility in the validation. There were also interlaboratory differences which should be studied further.

Future validation studies should include the modules necessary to predict CD variations through the paper machine, wet press, drier and calender sections for comparison with the measured CD property data.

The effects of OCC, refining, pressing and machine speed were surprisingly small for this grade. These effects were quantified in the following sensitivity study by using the simulation model to eliminate transient effects and interactions between variables.

## Model Modifications

Based on the results of this analysis, the following model changes will be made:

1. Reduce the CSF dependence of the wet compressibility model.
2. Change the modulus models so they depend on bulk density rather than bond density.
3. Change the Gurley porosity to depend on surface density rather than bulk density.
4. Increase the sensitivity of CSF to specific power for lower yield furnishes in the refiner models.

## SENSITIVITY ANALYSIS

The sensitivity analysis was performed using the model with Reel 1 conditions as the basis for determining the expected affect of four major test variables on end-user performance. By changing only one variable at a time using the model, it was possible to obtain unambiguous estimates of the decoupled sensitivity of each property to a specific variable. The four parameters were varied, as follows: (1) OCC content - $18 \%$ to $38 \%$, (2) hole \& tickler refiner loads - minimum to maximum values, (3) press load - minimum to maximum values, and (4) calender stack - loaded or unloaded. The variable conditions are summarized in Table XXXIII.

The sensitivity study was done without changing any of the models. In light of the findings of the validation study, the sensitivity coefficients for the effect of calendering on tensile properties were assumed to be zero even though the current models predicted a drop in tensile, burst and stretch. The sensitivity coefficients for the contact areas and bond area PAT's, $S_{b 1}, S_{b 2}$ and $S_{a}$ may also change after the wet press densification model is modified.
