The vibrational spectra of the pentitols and erythritol were investigated. The Raman and infrared spectra of these crystalline compounds were measured from 4000 to approximately 150 wave numbers $\left(\mathrm{cm}^{-1}\right)$. Their spectra are complex and interpretive efforts are complicated by extensive vibrational coupling of the internal modes below $1500 \mathrm{~cm}^{-1}$. Consequently, detailed normal coordinate calculations were used in this investigation.

A series of computer programs were used to construct and solve the vibrational secular equation of ribitol, xylitol and erythritol. To solve each :secular equation required the use of explicit structural data and an approximate set "of intramolecular force constant parameters. The calculated frequency parameters derived from solving the vibrational secular equations were correlated with the experimentally measured frequencies. The difference between the calculated and experimental frequencies was used to formulate a basis for a refinement of the initial set of force constants. An iterative nonlinear least squares technique, based on the Fletcher-Powell method, was used to simultaneously adjust the force constants until the difference between the calculated and experimental frequencies were minimized. After refinement there was an overall average difference of $9.1 \mathrm{~cm}^{-1}$ between the calculated and assigned experimental frequencies.

The force field derived from the refinement process was shown to be capable of predicting the vibrational spectrum of D-arabinitol. The ability to predict the distribution of bands in the D-arabinitol spectra has clearly opened up the possibility of extending this approach to other alditols. As a matter of interest, the observed spectra of both $D$ and $D, L-a r a b i n i t o l ~ w e r e ~ c o m p a r e d . ~ D i f f e r-~$ ences in their spectra were noted and have been attributed to suspected
differences in the geometry of their unit cells and/or differences in the intermolecular hydrogen bonding.

The results of the analyses demonstrate that the vibrational spectra of the pentitols and erythritol can be understood in terms of a relatively simple force field. The major differences among the pentitol spectra result primarily from changes in the vibrational coupling caused by the structural differences among the isomers. This suggests that most of the molecular vibrations arise, to a first approximation, from the isolated molecule, apart from its environmental surroundings. Although interactions among the molecules in the unit cell were detected, the effects on the spectra were localized in particular bands. The effects of hydrogen bonding appear to be of secondary importance in understanding the vibrational spectra of these compounds. The overall band distribution is most sensitive to the coupling of the atomic vibrations within the molecule.

Attempts to analyze comprehensively the vibrational spectra of carbohydrates ${ }^{l}$ have been renewed recently in an effort to broaden the application of vibrational spectroscopy as a tool for studying the physical chemistry of these complex molecules. Interest has been particularly aroused because of the importance of the saccharides in the technology of natural products and in medicine.

For example, in nature the saccharides often occur in polymeric form such as the anhydroglucose polymer cellulose. Cellulose, which is one of the few abundant and renewable natural resources, is a basic raw material for the textile and paper industries. Also the saccharides are biologically important structural components in living tissues, and are involved in metabolic pathways: (l) glycolysis and alcoholic fermentation, and (2) pentose phosphate metabolism. Furthermore, they enter into a number of important biochemical mechanisms such as blood coagulation and antigen antibody interactions, and they are constituents of some of the clinically important antibiotics.

Even though some progress has been made in the interpretation of carbohydrate spectra, much remains to be done before the potential of vibrational spectroscopy is fully realized. The infrared (IR) spectra of the saccharides have been investigated quite extensively. However, the complexity of the spectra and the difficulties in resolving the lower frequency regions have limited the progress of interpretive efforts. Most interpretive efforts have necessarily relied on the group frequency approach. The group frequency approach is an empirical

[^0]method based on the assumption that vibrations for a certain atomic group (e.g., $C=C$ bonds) are independent of the rest of the atoms in the molecule. Thus, by comparing the spectra of a large number of compounds having a common group, it is possible, in some instances, to find absorption bands which remain relatively constant. The frequency of these bands can then be considered to be characteristic of the vibrational motion of the common atomic group.

However, due to the similarity of the atomic groupings in many carbohydrate molecules, the majority of the bands are thought to result from complex mixtures of vibrational motion (i.e., most of the frequencies are combinations of many kinds of motion coupled together). Thus, it is difficult to make comprehensive interpretations from systematic comparisons of the carbohydrate spectra with the spectra of simple compounds which have been interpreted more completely. Some regions, like the fingerprint region, simply cannot be interpreted using this approach.

Although interest in developing vibrational spectroscopy as a tool in physical chemical investigations of the carbohydrates has existed for some time, the interest and the methodology necessary to expand the application have not always coincided. Consequently, vibrational spectroscopy (mostly IR) has functioned primarily as an analytical tool in investigations relating to the chemistry of the saccharides. However, now the methodology does exist. Developments in both experimental and computational techniques in the field of spectroscopy have made possible more rigorous analyses of the spectra of complex molecules possessing more than 20 atoms.

More specifically, the availability of laser Raman spectrometers and the gradual development of more effective computer methods for normal coordinate calculations have been responsible for the most recent advances. Improved

Raman spectrometers provide complementary spectral information to IR absorption measurements, and the normal coordinate calculations allow for the detailed investigation of the vibrational dynamics of large molecules. Thus, these advances suggest that comprehensive analyses of the spectra of certain carbohy-drate-related molecules are now possible. The results obtained from further analyses would considerably advance our basic understanding of the vibrational dynamics of these molecular systems.

The thesis research reported here is actually one part of a broader effort to analyze systematically and eventually interpret the vibrational spectra of various anhydroglucose polymers, including cellulose. It is felt that, in order to accomplish this broader goal, two inseparable problems must be solved: (1) interpreting the spectra of the pyranoses, and (2) interpreting the spectra of the anhydroglucose polymers. Similarly, understanding the spectra of the pyranoses requires an understanding of the spectra of simpler though structurally related carbohydrate: compounds, such as the 1,5 -anhydropentitols (1,5-AHP's) and the pentitols.

A comprehensive study of the solid-state vibrational spectra of the 1,5AHP's has recently been completed (1). The major portion of this thesis examines the solid-state vibrational spectra of (I) ribitol, (II) xylitol, (III) D-arabinitol (the pentitols) and (IV) erythritol.

The purpose of the investigation is to analyze the spectra of these compounds and to provide information to assist in the spectral interpretation of other related carbohydrate molecules.

## BACKGROUND

There are numerous: difficulties involved in interpreting the spectra of the carbohydrates. First, the spectral bands are often crowded and the problem of assigning and interpreting the individual modes is extremely difficult. Secondly, below $1350 \mathrm{~cm}^{-1}$ the origins of the vibrations are likely to involve more than a localized vibration of a specific group within the molecule. Deuteration work has long suggested this possibility (2, $\underline{3}$ ). In the IR spectra of cellulose and xylan, for instance, there are about 17 bands between 1500 $980 \mathrm{~cm}^{-1}(\underline{2})$. Of these, the bands between $1500-1200 \mathrm{~cm}^{-1}$ have been accounted for as either $O H$ in-plane (ip) or CH and $\mathrm{CH}_{2}$ bending modes (2). As a result, much of the work has been confined to the region between $1100-700 \mathrm{~cm}^{-1}$ : For example, bands between $1075-980 \mathrm{~cm}^{-1}$ in the spectra of cellulose, laminarin, amylose, and $x y l a n$ have been interpreted as $C O$ and $C C$ stretching modes (4). However, further clarification of some of the spectral features in this region is required ( 2,4 ).

The status of the work prior to 1964 has been described in a comprehensive review by Spedding (르).. Most of his discussion related to work on the IR spectra of the carbohydrates. Essentially two methods were used for interpretive purposes in the region between $960-730 \mathrm{~cm}^{-1}$ in the spectra of carbohydrates. One method was based on the correlation of features in the IR spectrum of tetrahydropyran (THP) with similar features in the spectra of the pyranoses and related carbohydrates. Bands associated with particular ring vibrations in the THP molecule were correlated on the basis of their frequencies and intensities to similar bands appearing in pyranose compounds. This is an example of the use of structurally simpler compounds to help understand the spectra of more complex molecules.

The other method focused on spectral features associated with the anomeric carbon atom. In this method a wide range of compounds having similar atomic groupings at the anomeric carbon atom were compared. Frequencies in the spectra of these compounds which remain constant were assigned to modes involving the atoms associated with the anomeric carbon atom.

Important contributions have been made by a number of workers which have, for the most part, utilized both of these methods. Tipson's (5) review in 1968 provides a comprehensive discussion of the characteristic infrared bands shown by various atomic groups in carbohydrate molecules.

Polarized IR spectra have also been used for interpretive purposes in the CH stretching region, $3000-2800 \mathrm{~cm}^{-1}$, of cellulose. Marchessault assigned the $2853 \mathrm{~cm}^{-1}$ band in cellulose to the symmetric $\mathrm{CH}_{2}$ stretching mode based on IR polarization data (6).

Deuterium substitution has been used effectively in some cases to identify OH bending modes. Also, by comparing the spectra of cellulose with the spectra of deuterated cellulose and related polymers, the bands between $1075-980 \mathrm{~cm}^{-1}$, mentioned earlier, were interpreted as $C O$ and $C C$ stretching modes (4).

In the early 1960's progress in the methodology of vibrational spectroscopy led to another approach to analyzing the spectra of complex molecules. The work of Schachtschneider and Snyder ( 7,8 ) on the hydrocarbons and of Snyder and Zerbi (9) on the ethers, including THP, established that systematic normal coordinate (NC) analyses of the spectra of groups of related compounds was possible.

An NC analysis is a mathematical treatment designed to calculate the fundamental vibrations (i.e., normal modes) of a molecule and to analyze the motions associated with these vibrations. In a nonlinear polyatomic molecule of $\underline{n}$ atoms there are $3 \underline{n}-6$ vibrational degrees of freedom. Thus, theivibrational spectra of a nonlinear molecule will reveal $3 n-6$ fundamental frequencies ${ }^{2}$. Each observed fundamental frequency represents a normal mode, which can be described by an associated normal coordinate. The normal coordinate may be a mixture of various internal displacement coordinates such as bond stretching or angle deformations. One objective of the analysis is to resolve this mixture into its major components. When a particular mode is excited, all the atoms involved oscillate in phase with the same angular frequency. Depending on the masses of the atoms and the nature of the bonds the amplitudes may be different: By correlating the $3 n-6$ calculated normal modes with the experimentally observed frequencies it is possible to interpret the vibrational spectrum.

Prior to the analyses of Snyder and Zerbi on the ethers, some interpretive work had been done on THP as reviewed by Spedding (2). In particular, Burket and Badger (10) examined the infrared spectrum of THP and assigned various bands between 1060 and $800 \mathrm{~cm}^{-1}$ to ring stretching vibrations [including the symmetric (sym.) and asymmetric (asym.) C-0-C stretch]. Their interpretation of THP was based on the NC analysis of cyclohexane by Becket, et al. (11). However, the actual NC analysis of THP (and related ethers) by Snyder and Zerbi was not completed until 1967. More recently, Pickett and Strauss (12) adapted the computational methods of Schachtschneider and Snyder in a study

[^1]of the ring bending vibrations of cyclohexane and related oxanes including THP. They determined the ring bending potential of the various oxanes using the NC analysis and used this information to calculate rate constants for chair to boat conversion.

Three other investigations have been completed in the early 1970's in an effort to develop the basis for an interpretation of the vibrational spectra of some of the more important saccharides. First, Vasko (13) examined the Raman scattering of a large number of carbohydrates. He also computed the
 published literature on more simple molecules and structural data based on the neutron diffraction work of Brown and Levy cited in (14). Even though no structural approximations were necessary, there were serious gaps between the computed and experimental band distributions suggesting the need for an improved set of force constants.

Secondly, Pray (4) made an a priori calculation of the skeletal planar vibrations and internal vibrations of certain atomic groups in cellulose using the "multiple origin method" of Deeds (15) and initially selected constants from Wilson, et $\underline{\text { al }}$. (16) and Takahashi, et al. (17). An approximate structural model of glucose was used by Pray as a simplified cellulose model. To simplify the calculations the coupling between in-plane (ip)! and out-of-plane (op). vibrational motions [i.e., the plane formed by the $C(1), C(3)$, and $C(5)$ atoms] was neglected. However, the spectral interpretations resulting from Pray's analysis are not consistent with prior knowledge relating to the vibrational spectra of the carbohydrates.

Although both of these latter investigations represent attempts to analyze mathematically the molecular vibrations of glucose, the results
suggest that the complexity of the problem requires (I) a more systematic approach (such as that taken by Snyder and Zerbi) and (2) a more representative intramolecular force field. Pitzner's (1) investigation of the l,5-AHP compounds, mentioned earlier, supports this view. He was able to successfully analyze the vibrational spectra of the 1,5-AHP molecules using a procedure for the analysis similar to the one developed by Schachtschneider (18,19). In each case, the computed spectra approximated the observed spectra reasonably well. Furthermore, the interpretations, based on an analysis of the calculated normal coordinates, were determined to be consistent with prior experience about carbohydrate spectra using group frequency correlations. Intramolecular force constants representative of the l,5-AHP's were calculated by making simultaneous adjustments to an initial set of force constant values until the difference between the calculated and experimental frequencies were minimized. The values of the initial constants were taken from Snyder and Zerbi's NC analysis of THP and related ether compounds.

More importantly, Pitzner found that the numerous differences in the location of the observed spectral bands among the 1,5-AHP's were primarily due to $\mathcal{G}_{\text {matrix }}$ effects or kinetic energy effects as they are sometimes called ${ }^{3}$. Kinetic energy effects result from structural differences among related molecules (these can be either configurational or conformational differences). In the case of the l,5-AHP molecules the primary structural difference is configurational and related to the orientation (either axial or equatorial) of the vicinal hydroxyl groups. These structural changes alter the vibrational

[^2]coupling among the oscillations associated with the fundamental vibrations. Because the coupling patterns are altered the frequencies and intensities of the vibrations change.

The success of Pitzner's NC analyses of the l,5-AHP compounds has clearly opened up the possibility of extending this approach to more complex carbohydrate molecules.

## THESIS OBJECTIVES

The major objective of this thesis was to provide a basis for the interpretation of the vibrational spectra of the alditols. To achieve this objective, erythritol, ribitol, xylitol, and D-arabinitol were selected as representative alditols. Normal coordinate analyses of the molecular vibrations of these molecules were carried out in an effort to formulate an interpretive basis for this class of compounds.

Pitzner's work on the l,5-AHP's (1) clearly established the possibility of developing a force field for the alditols. A force field with some predictive capability would provide a basis for an interpretation of the alditol spectra. Thus, the problems confronted in this investigation were twofold:
(1) Develop the best possible force field for these selected models.
$\left(2^{\prime}\right)^{*}$. Determine the transferability of this force field to related alditol molecules.

Three of the four alditols, ribitol, xylitol, and erythritol were used to develop a common force field. These compounds were selected for several reasons. First, their crystal structures have all been determined. Thus, with direct structural data available no approximations were necessary with regard to the conformations adopted by the molecules in the solid state. The fourth molecule, D-arabinitol, was excluded from the development because its structure is unknown. Hunter and Rosenstein (20) have determined the crystal structure of $D, L$-arabinitol. However, there is no basis for assuming that the structure of the $D$ isomer in D,L-arabinitol is the same as its structure in the crystalline D isomer. This uncertainty may be resolved by comparing both the $D$ and, $D, L$ spectra with the calculated spectrum of the $D$ isomer as it exists in the $D, L$ crystal. Secondly, ribitol and xylitol are structurally related to both the l,5-AHP's and the
pentoses. They possess the same relative configuration at $C(2), C(3)$, and $C(4)$ as the corresponding members in the other two groups. •The atomic groups at these three locations are identical. Thus, the constants in the force field developed by Pitzner could be used as an initial approximation to the force field of the alditols.

Finally, xylitol and ribitol have similar "flexed" chain conformations while erythritol has an "extended" chain or planar zigzag conformation. The flexed chain conformation is characterized by rotation about a CC bond which alters the otherwise planar zigzag conformation of the carbon backbone. A parallel interaction between $\mathrm{C}_{2} \mathrm{O}$ and $\mathrm{C}_{4} \mathrm{O}$ (i.e., a syn-axial interaction) in both ribitol and xylitol is relieved by a $120^{\circ}$ rotation about $C(2)-C(3)$ or about $C(3)-C(4)$ as shown in the following equations.

These two kinds of conformations (i.e., the flexed and the extended chain) are characteristic of the tetritols, pentitols, and hexitols (21). Thus, these three compounds are structurally representative of the alditols. A field capable of describing the intramolecular forces in each of these molecules would be expected to transfer reasonably well to other alditols possessing either type of conformation.

To develop a force field for the alditols, the vibrational spectra of ribitol, xylitol, and erythritol were computed by solving their vibrational secular equations. Based on these calculations the computed frequencies were
correlated with experimentally measured frequencies. An effort was then made to reduce the least squares deviation between the two sets of data by a succession of adjustments to the common force constants in the $\underset{m}{F}$ matrices of these model compounds. Thus, the approach to the solution of the first problem had: four essential steps:
(1) Measure the observed vibrational frequencies of ribitol, xylitol, and erythritol.
(2) Compute the vibrational frequencies of each molecule, given the necessary structural data and an initial set of common force constants.
(3). Assign the calculated modes to the measured frequencies of vibration.
(4) Refine the initial force constants by minimizing the least-squares deviation between the observed and calculated frequencies.

Several important constraints were imposed on the fourth step. The first constraint related to the actual refining process. The total number of refined force constants was not allowed to exceed the number of known experimental frequencies. Pitzner established that it was possible to develop a force field for the $1,5-A H P ' s$ by perturbation of existing parameters. However, to maximize the interpretive value of the constants obtained from such treatments it is important that these parameters be capable of reproducing a number of independent experimental frequencies which is greater than the number of variables used in the refinement.

Secondly, it was required that the spectral interpretations based on the NC analyses be consistent with prior experience in group frequency correlations. Finally, the final values of the constants were expected to be consistent with the values of similar constants in related molecular systems. In this regard, however, some differences between the initial and final constants were
anticipated in view of the differences between the pentitols and the $1,5-A H P^{\prime} s$. The absence of both the ether linkage and the ring structure were expected to affect some of the constants. Also, the chainlike structure of the alditols may affect the degree of intermolecular hydrogen bonding between the vicinal hydroxyl groups. Such an effect would be expected to result in differences among similarly defined force constants.

The second objective was to test the transferability of the constants developed by minimizing the least squares deviation between the observed and calculated data for ribitol, xylitol, and erythritol. Although force fields have been developed for the $\underline{n}$-paraffins (7), aliphatic ethers (9), and l,5-AHP's using perturbation treatments, transferability of the force constants to related molecules has not been demonstrated. A third pentitol, D-arabinitol, was used to determine whether the constants could be applied to related molecules. Using the available data on the structure of D-arabinitol as it exists in the $D, L$ crystal and the final set of refined force constants, the spectrum of the molecule was calculated. A reasonable correlation between the calculated and observed bands in the D-arabinitol spectra (Raman and IR) would provide a measure of the predictive capabilities of the field.

## EXPERIMENTAL

SAMPLE PREPARATION

With the exception of D,L-arabinitol, all other compounds were available from commercial sources. The D,L-arabinitol crystals (m.p. $=105^{\circ} \mathrm{C}$ ) were obtained by slow evaporation from a (95/5, v/v) ethanol-water solution of an equal molar mixture of the $D$ and $L$ isomers. Deuteration of the hydroxyl groups of ribitol, xylitol, and erythritol was accomplished by repeated crystallization from monodeuterated ethanol $-\mathrm{D}_{2} 0$ mixtures ( $75: 20, \mathrm{v} / \mathrm{v}$ ). The deuterated crystals were separated by filtration, washed with small amounts of monodeuterated ethanol, and dried in a vacuum desiecator. The degree of deuteration was not rigorously established.

The Raman spectra were measured with a Spex Raman system with a Coherent Radiation Model 52A Argon ion laser source. A laser frequency of 5145 A (19435 $\mathrm{cm}^{-1}$ ) was used. The slit widths were set for a minimum resolution of $5 \mathrm{~cm}^{-1}$.

The Raman spectra of the solid samples were obtained using pressed powder pellets mounted in a $180^{\circ}$ back-scattering arrangement. The beam was focused directly upon the face of the pellet. Before scanning the crystalline pellets were exposed to the laser beam for a time interval of approximately 50 minutes to allow the fluorescence to diminish. The solution spectra were obtained from concentrated aqueous samples sealed in capillary tubes mounted in the standard sampling mode.

The standard procedure for preparing pellets was modified somewhat for the deuterated samples to minimize hydrogen-deuterium exchange with water vapor.

The powder and die for pressing the pellets were prepared in an anhydrous air bag. Also, the time interval before scanning was reduced as much as possible.

Infrared spectra of the powdered solids were recorded with a Perkin-Elmer 621 IR spectrometer using KBr pellets prepared in the standard manner.

## COMPUTER PROGRAMS

The computational work was performed on an IBM 360 Model 44 digital computer. The vibrational problem was set up in terms of internal displacement coordinates using the Wilson GF method (16). The programs for solving the secular equations were developed by Schachtschneider (18,19) and adapted for the IBM 360 OS operating system by Pitzner (1). The function minimization algorithm of Fletcher and Powell (.22) was used for the nonlinear least-squares refinement of the force constants. These programs are on permanent file in the computer center library at The Institute of Paper Chemistry (Library Source Tape: IPC.TH.OOL).

RIBITOL

The Raman spectra of ribitol and deuterated ribitol are shown in Fig. 1. Solution spectra in both $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{D}_{2} \mathrm{O}$ are shown in Fig. 2. An $I R$ spectrum of $a$ KBr mounted ribitol sample appears in Fig. 3. The frequencies of the observed bands in each spectrum are listed in Table I.

XYIITOL

The Raman spectra from pellets of $x y l i t o l$ and deuterated $x y l i t o l$ are shown in Fig. 4 along with an $\mathrm{H}_{2} \mathrm{O}$ solution spectrum. An IR spectrum of xylitol is shown in Fig. 3. The frequencies of the observed bands in each spectrum are listed in Table II.

## ERYTHRITOL

Aside from the conformational differences and differences in the location and degree of intermolecular bonding, erythritol possesses another property not characteristic of the other alditols. The basic structural backbone of the erythritol molecule is reported to have a center of symmetry (23). The unit cell is also centro-symmetric. In centro-symmetric molecules, transitions that are allowed in the IR are forbidden in the Raman spectrum. The converse is also true. The Raman and IR spectra of erythritol are shown in Fig. 5. An $\mathrm{H}_{2} \mathrm{O}$ solution spectrum (Raman) is shown in Fig. 5 also. The IR spectra of erythritol and deuterated erythritol are compared in Fig. 6. The measured frequencies in each spectrum are tabulated in Table III. From Table III it is apparent that the rule of mutual exclusion is not rigorously obeyed.

## ARABINITOLS

The spectra of D,L-arabinitol were measured in an effort to determine whether there were any significant differences between the spectra of the racemic form and the spectra of the $D$ and $L$ isomers. The Raman and IR spectra of $D$ and D,L-arabinitol are compared in Fig. 7 and 8, respectively. The frequencies of the observed bands are listed in Table IV. Since the L spectra are identical to the $D$ spectra, they have not been reported. From Fig. 7 and 8 it is apparent that the spectra of these two crystalline forms are different. The nature of the observed differences will be discussed in detail later.

By comparing the frequencies of the observed bands in the solid-state spectra of the pentitols, differences are seen to occur in all regions. Also, the Raman spectra recorded for concentrated $\mathrm{H}_{2} \mathrm{O}$ solutions of ribitol, xylitol, and erythritol are distinctly different in many regions when compared to the spectra of the powdered solids. Broadening due to solute-solvent interactions limited the resolution of many bands. This was especially true of the CH stretching region. However, a major departure from the solid-state spectra was, the appearance of new bands in the spectra of the solutions. The new bands usually appeared in the regions below $1100 \mathrm{~cm}^{-1}$.

## VIBRATIONAL ANALYSES

The central part of the analysis is the solution of the vibrational secular equation. The equation arises as the condition for the existence of simultaneous solutions to the differential equations describing the motion of a molecule in each of the different degrees of freedom.

[^4]Wilson, et al. (16) have described in detail the essential elements of the theory behind the NC analysis of molecular vibrations. The mathematical treatment of the vibrations is initiated by defining the kinetic and potential energies of a model in terms of a suitable set of coordinates. The model is generally specified to consist of (1) point masses representing the atoms and (2) force constants which represent the intramolecular forces holding the atoms in an equilibrium configuration.

From the kinetic and potential energies of the model it is then possible to derive the differential equations which describe the vibrational motion of the model. The simultaneous solutions to these differential equations result in a. set of algebraic equations. In terms of internal coordinates, these equations, in matrix form, may be expressed as

$$
\begin{equation*}
\left(\mathrm{GF}_{n}-\lambda_{\mathrm{k}} \underset{\sim}{\mathrm{E}}\right) \underset{m \times k}{]_{\mathrm{k}}}=0 \tag{1}
\end{equation*}
$$

where

$$
\begin{aligned}
& \underset{\sim}{G}=\text { the inverse kinetic energy matrix } \\
& \underset{m}{F}=\text { force constant matrix } \\
& \lambda_{\underline{k}}=\begin{array}{l}
\text { frequency parameters }=4 \pi^{2} \nu_{k}^{2} \\
\text { frequency of the oscillator })
\end{array} \text { (where } \nu_{\underline{k}}^{2} \text { is a fundamental } \\
& \underset{\sim}{E}=\text { unit matrix } \\
& \begin{array}{l}
\underline{\underline{k}}=\text { is a column vector of the amplitudes of the various } \\
\text { displacement coordinates in the kth vibration. }
\end{array}
\end{aligned}
$$

There are three components in Equation (1):
(1) the structure of the molecivlar model,
(2) the force constants,
(3) the vibrational frequencies.

The G matrix is easily derivable from known structural data. Thus, in systems where the force constant matrix (i.e., the $\underset{\sim}{F}$ matrix) is known, the solution to the vibrational problem is straightforward. The $3 \underline{n}-6$ frequency parameters (or $3 n-5$ for linear molecules) can be evaluated directly. The eigenvalues, $\lambda_{\underline{k}}$, are the roots of the secular determinant (i.e., characteristic equation)

$$
\begin{equation*}
\operatorname{det}\left(G F-\lambda_{k} E\right)=0 \tag{2}
\end{equation*}
$$

Equation (2) is the vibrational secular equation. Solving this equation is fundamental to the NC analysis process.

In the present instance, however, the elements of the $\underset{\sim}{F}$ matrix are unknown. They may be obtained by a method of successive iterations beginning with approximations to the force constants in the $F$ matrix. The calculated frequency parameters (i.e., eigenvalues of GF) will not be equal to those derived by experiment. The differences between the observed and calculated frequencies form a basis for determining better approximations of the force constant parameters in the $\underset{\sim}{F}$ matrix.

The basic framework used for the NC analyses was based on the Wilson ,GF method (16) and Pitzner's (1) modification of programs developed by Schachtschneider (18,19). It involves a sequence of iterations in which a set of force constant parameters, $\Phi_{\underline{i}}$, are adjusted to reduce the least-squares deviation between observed frequencies, $\lambda_{\text {obs. }}$, and calculated frequencies, $\lambda_{\text {cal. }}$, such that

$$
\begin{equation*}
Q^{r}=\sum_{k} P_{k}\left[\lambda_{k(o b s .)}-\lambda_{k(c a l .)}\right]^{2} . \tag{3}
\end{equation*}
$$

In Equation (3), $\underline{Q}^{\underline{r}}$ is the value of the sum of the squared residuals after the $\underline{r} t h$ iteration. ${\underset{\mathrm{P}}{\mathrm{k}}}^{\text {is }}$ an element of an arbitrary weighting matrix $\underset{\sim}{P}$. The sum Q is a "function" of the independent force constant parameters. That is, if any parameter $\Phi_{\underline{i}}$ is varied, a change in $\underline{Q}$ will result. Therefore, we can consider the parameters $\Phi_{\underline{i}}$ as independent "variables" and $\underline{Q}$ is a "function" of these "variables."

A nonlinear least-squares refinement method developed by Fletcher-Powell (22) (FP) and employed by Pitzner (1) in his study of the l, 5-AHP's was used. Gans (24) has also used the FP minimization algorithm successfully. The main features of the NC analyses and nonlinear least-squares refinement of the force constants are shown in Fig. 9. The flow diagram can be divided in four basic parts:
(1) Data input,
(2) Solving the secular equation,
(3) Refining the initial constants using the FP method, and
(4) Results.

DATA INPUT

The Internal Coordinates Chosen for the NC Analyses
These coordinates were defined in accordance with the suggestions of Decius (25). The three types of internal valence coordinates used to describe the vibrational displacements were: (1) valence bond stretching; (2) valence angle bending; and (3) torsion. For the pentitols, 65 internal coordinates were defined to describe each molecule. Since each of these molecules has 60 internal degrees of freedom, there are 5 implied redundancies. These are local and removable, but they are included to facilitate the construction of a

Figure 9. General Flow Diagram for the Basic Force Constant and Normal. Coordinate Calculations
simplified valence quadratic force field. There are 21 valence bond.stretching coordinates, 35 valence bond angle bending coordinates, and 9 torsional coordinates.

A total of 52 internal coordinates were used to describe erythritol. These included 17 valence bond stretching coordinates, 28 valence angle bending coordinates, and 7 valence angle torsion coordinates. Since erythritol has 48 internal degrees of freedom, there are four redundancies. The significant input data appear in Appendix I. Tables XVIII-XX describe the internal coordinates for each of the four molecules.

The G Matrix
The number of internal coordinates used to define the vibrational motion of a molecule also determines the order of its $G \underset{\sim}{G}$ matrix. Thus, the $G$ matrix of erythritol would be of lower order than the ${ }^{G}$ matrices of the other alditols. Of general significance is the fact that the $G$ matrix depends only on the masses of the atoms and the geometry of the molecule. Also, the $G$ matrix is always symmetric and always positive definite, that is, its eigenvalues are all real and positive.

More formally, the $\underset{\sim}{G}$ matrix is defined in terms of the atomic masses and a transformation matrix commonly referred to as the $\underset{\sim}{B}$ matrix. The $\underset{\sim}{B}$ matrix is defined in the following expression

$$
\begin{equation*}
\underset{\sim}{S}=\underset{N}{B X} \tag{4}
\end{equation*}
$$

where
$S_{N}=$ internal displacement coordinates expressed as a vector $\underset{\sim}{X}=$ cartesian displacement coordinates expressed as a vector.

The $B$ matrix is rectangular with $3 n$ columns and as many rows as there are internal coordinates. The G matrix is usually given as

$$
\begin{equation*}
\underset{\sim}{G}={\underset{\sim}{B}}^{-1} \mathbb{N}^{\prime} \tag{5}
\end{equation*}
$$

where $\quad{\underset{\sim}{-1}}^{-1}=$ diagonal matrix of order $3 n$ whose elements are the inverses of the atomic masses each being present 3 times ${\underset{\sim}{N}}^{\prime}=$ transpose of the $\underset{\sim}{B}$ matrix.

The specific details of the $G$ matrix development are presented elsewhere by Wilson, et al. (16).

To determine the $\underset{\sim}{G}$ matrix it is necessary to calculate the cartesian coordinates of the "atoms" in the alditol models. These coordinates were computed from the internal coordinates. The structural data necessary for these computations is specified in Appendix I. The bond lengths and bond angles of xylitiol, ribitol, erythritol and D-arabinitol are specified in Tables XXI-XXIV. The "atoms" in each of these molecular models were numbered in the manner depicted in Fig. 21.

The coordinates of ribitol and xylitol are based on their respective crystal structures determined by Jeffrey, et al. (26,27) using x-ray diffraction techniques. As previously mentioned, the structural data for D-arabinitol was based on the structure of the D.isomer in the D,L crystal (20). However, the: " structural data for erythritol was obtained from several sources. The bond distances and angles of all coordinates not involving hydrogen atoms were taken from the structural data of Bekoe and Powell (23). The remaining internal coordinates were estimated by averaging the appropriate coordinates from the crystal structures of the other ailditols.

In all cases an average bond length of 0.97 A was used for OH coordinates, 1.093 A for methylene CH coordinates, and l.l20 A for the methine CH coordinates. These distances are longer than thosereported for the alditols, but are consistent with thermodynamic and neutron diffraction data. Likewise, an average value of $110.0^{\circ}$ was used for all COH bond angles and $109.0^{\circ}$ for all CCH bond angles. These values represent averages taken from neutron diffraction studies on $\alpha-D-g l u c o s e ~(28), \beta-D-g l u c o s e(29)$, and $D-t a r t a r i c$ acid (30).

The resulting $G$ matrices of xylitol, ribitol, erythritol, and D-arabinitol are reported in Tables XXV-XXVIII, respectively. Each $\underset{\sim}{G}$ matrix is unique. There are, for example, 855 nonzero elements in the $G$ matrices of ribitol, xylitol, and D-arabinitol. Of these there are 806 elements in the $\mathcal{G}$ matrix of ribitol that have significantly different values than corresponding elements in the $\underset{\sim}{G}$ matrix of $x y l i t o l, ~ a n d ~ 803$ elements which are different than corresponding elements in the $\underset{\sim}{G}$ matrix of D-arabinitol.

The Z Matrix
Before solving the vibrational secular equation, explicit form must be given to the $\underset{\sim}{F}$ matrix. The force field selected for use in this study is empirical and is an extension of the fields developed by Pitzner (I), Snyder and Schachtschneider (8), and Snyder and Zerbi (9). The field is called a "Simplified Valence Quadratic Force Field" (SVQFF) after Pitzner.

For reasons of convenience, both in the solution of Equation (2) and in the nonlinear refinement of the force constants, the $\underset{\sim}{F}$ matrix is not evaluated directly, A transformation matrix is used instead. The $Z$ matrix, which is sometimes referred to as the constraint matrix, is defined by the expression

$$
\begin{equation*}
F_{i j}=\sum_{k} Z_{i j k} \Phi_{k} \tag{6}
\end{equation*}
$$

 each of the alditol compounds are reported in. Tables XXIX-XXXIII.

Whereas the $\underset{\sim}{Z}$ matrix is a mathematical formalism, the $\underset{\sim}{F}$ matrix is an integral part of a mathematical expression for an important physical quantity, the potential energy V. For small values of atomic displacement the potential energy in terms of internal coordinates is

$$
\begin{equation*}
V=\frac{1}{2} \sum_{k, 1}^{3 n-6} F_{k l} S_{k} S_{1} \tag{7}
\end{equation*}
$$

where $\underline{\underline{S}}_{\underline{\underline{k}}}$ and $\underline{\underline{S}}_{\underline{1}}$ represent internal displacement coordinates. Actually, the upper limit on the series expansion [Equation (7)] is determined by the total number of internal coordinates used to describe the model and not the $3 \underline{n}-6$ degrees of freedom, Equation (7) is derived from a Taylor series expansion of $\underline{V}$ as a function of the internal displacement coordinates $\underline{S}_{\underline{k}}$ :

$$
\begin{align*}
2 V & =2 V_{o}+2 \sum_{k}\left(\partial V / \partial S_{k}\right)_{0} S_{l}+\sum_{k, 1}\left(\partial^{2} V / \partial S_{k} \partial S_{l}\right)_{0} S_{k} S_{l}+\ldots \text { higher terms } \\
& =2 V_{0}+2 \sum_{k} F_{k} S_{l}+\sum_{k, 1} F_{k l} S_{k} S_{l}+\ldots \text { higher terms. } \tag{8}
\end{align*}
$$

If the potential energy is chosen to be zero at the equilibrium configuration, then $\underline{V}_{\underline{o}}=0$. In this configuration all the $\underline{\underline{S}}_{\underline{\mathrm{k}}}$ 's are zero because the atoms are all in their equilibrium positions. Thus, the potential energy must be at a minimum or

$$
\begin{equation*}
2 \sum_{k} F_{k} S_{1}=0 \tag{9}
\end{equation*}
$$

since $\left(\partial \underline{V} / \partial \underline{S}_{\underline{k}}\right)_{0}=0$.

Also, for small amplitudes of vibration, the higher order terms can be neglected so that the potential energy is

$$
V=\frac{1}{2} \sum_{k, 1} F_{k l} S_{k} S_{1} .
$$

The $\mathrm{F}_{-\mathrm{kl}}$ terms represent quadratic force constants and are the elements of the F matrix.

In a polyatomic molecule, the number of quadratic force constants greatly exceeds the number of frequencies. A general quadratic force field (GQFF) would include all possible $\underset{\underline{\mathrm{k} 1}}{ }$ terms (since $\underset{\sim}{\mathrm{F}}$ is a symmetric matrix $\underset{\underline{\mathrm{k} 1}}{ }=\underline{\underline{F}}_{\underline{1 \underline{k}}}$ ).
 zero and by grouping force constants which are likely to have similar values together. The assumption to assign many of the interaction terms a zero value is based on the likelihood that the potential interactions between nonconjugated bonds with no common nucleus are very small. The effect is to reduce the number of independent force constants; $\Phi_{\underline{i}}$, necessary to describe the force field of large, complex molecules.

Table $V$ defines the 59 force constant parameters used to specify the SVQFF of the alditol models. Each constant is defined in terms of an internal coordinate or interacting pairs of internal coordinates sharing common atoms. The first 21 constants in Table $V$ are referred to as "diagonal" terms because, as elements, they occupy positions along the diagonal of the symmetric $\underset{\sim}{F}$ matrix. The remaining 43 constants are "off-diagonal" or cross terms.

There are 8 valence bond stretching constants in Table V. Each stretching constant is associated with a particular atomic grouping. There are, however, only two basic types of atomic groupings: (A) the methine ( $\mathrm{C}-\mathrm{C}(\mathrm{H})-\mathrm{OH}$ ) and ( B )

[^5]the methylene ( $\mathrm{C}-\mathrm{CH}_{2}-\mathrm{OH}$ ). These are depicted in Fig. 10 and are appropriately designated in Table $V$.

(A) Methine

(B) Methylene

Figure 10. Different Atomic Groupings Defined

A similar distinction is made for the constants which relate to valence angle bending, but not for the torsion constants or the interaction constants. However, a distinction is made between a "trans" and a "gauche" bend-bend interaction when they are centered on adjacent carbon atoms. Figure 11 illustrates how some of the possible interaction force constants are defined. Only nearest neighbor interactions are considered. This implies that all stretch-stretch interaction constants must contain a common atom and all stretch-bend and bend constants must contain two common atoms.

SOLVING THE SECULAR EQUATION

There are many methods for solving secular equations. However, for large molecules digital computers and methods amenable to machine computation must be used. To compute the eigenvalues, $\lambda_{\underline{k}}$, of the secular determinant it is necessary to separate the GF matrix product from the $\lambda_{k} E$ product in Equation (1) such that

Stretch-Bend

Bend-Bend

 P

Figure 1l. Some Interaction Force Constants Defined

There will be equivalent expressions for each $\lambda_{\underline{k}}$. These equations can be combined. The vibrational equation can then take the form

$$
\begin{equation*}
\text { GFL }=\frac{I N}{} \tag{11}
\end{equation*}
$$

where $\Lambda$ is a diagonal matrix of the frequency parameters, $\lambda_{\underline{k}}$, and $\mathbb{I}_{\sim}$ is the transformation from normal coordinates, $\underset{\sim}{Q}$, to internal coordinates, $\underset{\sim}{\text { S }}$, such that

$$
\begin{equation*}
S=\underset{\sim}{L} . \tag{12}
\end{equation*}
$$

Equation (ll) can be solved by successive diagonalization using a digital computer. Although the product GF is not a symmetric matrix, it can be diagonalized by diagonalizing the two symmetric $\underset{\sim}{G}$ and $\underset{\sim}{F}$ matrices. The basic steps are shown in Fig. 9. The details are presented by Schachtschneider (I, 18, 19 ).

The G matrix is first diagonalized by an orthogonal transformation to give

$$
\begin{equation*}
\underset{\sim}{A} \underset{\sim}{\dot{A} A}=\underset{\sim}{D D} \tag{13}
\end{equation*}
$$

or

$$
\begin{equation*}
\underset{\sim}{G}=\text { ADPDA }_{\sim}^{\prime} \tag{14}
\end{equation*}
$$

where A is the orthogonal eigenvector matrix of $\underset{\sim}{G}$, and $\underset{\sim}{D}$ is a diagonal matrix whose elements are the square roots of the eigenvalues of $G$. A transformation matrix $\underset{W}{W}$ defined as

$$
\begin{equation*}
\underset{\sim}{W}=A D \tag{15}
\end{equation*}
$$

is then formed and applied to the $\underset{\sim}{F}$ matrix. A symmetric matrix $\underset{\sim}{H}$ results.

$$
\begin{equation*}
\underset{\sim}{H}=W^{\prime} \tilde{N}_{N} . \tag{16}
\end{equation*}
$$

The $\underset{\sim}{H}$ matrix is symmetric since $\underset{\sim}{A}$ is orthogonal and $\underset{\sim}{D}$ is diagonal. To sollve the secular equation, $\underset{\sim}{H}$ must then be diagonalized. The Jacobi method is used. The result may be expressed as

$$
\begin{equation*}
{\underset{\sim}{C}}^{-1} \underset{\sim}{H C}={\underset{\sim}{C}}^{-1} W_{\sim}^{\prime} \underset{\sim}{F} \underset{\sim}{C}=\Lambda \tag{17}
\end{equation*}
$$

where $\Lambda$ is the diagonal matrix of frequency parameters.

To calculate the normal coordinate associated with each normal mode, the $\underset{\sim}{L}$ matrix must be computed. Recall that the $\mathbb{J}$ matrix is the transformation from normal coordinates to internal coordinates. Multiplying Equation (17) from the left by first $\underset{\sim}{C}$ and then $\underset{\sim}{W}$ results in the following expression

$$
\begin{equation*}
W_{N} \cdot T W C N=W C A . \tag{18}
\end{equation*}
$$

Since WW $^{W}$ = G, Equation (18) becomes

$$
\begin{equation*}
\text { GFWC }=\mathrm{WCA} . \tag{19}
\end{equation*}
$$

Comparing Equations (11) and (19) it is obvious that the $\underset{\sim}{d}$ matrix may be defined a.s

$$
\begin{equation*}
\underset{\sim}{L}=\underset{\sim}{W C} . \tag{20}
\end{equation*}
$$

The eigenvalues which result from Equation (17) are directly related to the fundamental frequencies. The frequencies of the three alditol molecules selected for the refinement procedure were calculated using Pitzner's force constants developed for the l,5-AHP's (see Table V). The frequencies are listed in Table VI.

OPTIMIZATION OF THE FORCE CONSTANT PARAMETERS

The objective of the refinement is to minimize the least squares deviation between the observed and calculated frequency parameters. In the process an initial set of force constants are optimized using the Fletcher-Powell minimization algorithm. As shown in Fig. 9 the first step in the refinement results in the formation of $\underset{\sim}{J}$, the Jacobian matrix having elements ( $\partial \lambda_{\underline{k}} / \partial \mathrm{F}_{\mathrm{i} i}{ }_{\mathrm{i}}{ }^{r}$. The J , matrix is computed indirectly from the $\mathbb{L}$ matrix defined in Equation (20), since

$$
\begin{equation*}
J_{k i}=L_{i k}^{2} \cong \partial \lambda_{k} / \partial F_{i i} . \tag{21}
\end{equation*}
$$

The three general steps of the Fletcher-Powell algorithm are as follows:
(1) Compute a gradient vector $\underline{g}^{r}$ having elements $\frac{\underline{\underline{g}} \underline{\underline{i}}}{\underline{\underline{r}}}=(\partial \underline{Q} / \partial \Phi \underline{\underline{i}}) \underline{r}$, where $\underline{\underline{r}} \underline{\underline{r}}$ represents the $\underline{i t h}$ element of the gradient vector after $\underline{r}$ iterations.
(2) Determine a direction along which to make a desired move.
(3) Compute a step-size, $\underline{t}$, and move in the desired direction.

| 1164 | 61 | 1181 | 70 |  |  |

The calculation of the $J$ matrix and the subsequent formation of the JZ matrix are necessary steps in the computation of the gradient vector. In matrix notation $\underset{\sim}{\text { g }}$ may be written as

$$
\begin{equation*}
\underset{\sim}{\underset{\sim}{r}}=-2\left(\underset{\sim}{J}{ }_{\sim}^{r}\right)^{\prime} \underset{\sim}{p} \overline{\Delta \lambda}^{r} \tag{22}
\end{equation*}
$$

where $\overline{\Delta \lambda} \underline{\underline{r}}$ is defined to be a matrix of the elements $\Delta \lambda \frac{\underline{\underline{I}}}{\underline{I}}=\mid \lambda_{\underline{k}}$ (obs.) $\left.\lambda \frac{\underline{r}}{\underline{k}}(c a l) \right\rvert\,$. .

From Equation (22) it is evident that when $\underline{g}^{\underline{r}}$ is zero, either $\overrightarrow{\Delta \lambda^{n}}$ is zero, and the experimental frequencies are fitted exactly, or ( $J_{\sim}^{r}-Z$ ) is singular and $\underline{Q}$, the sum of the squared residuals, is not and cannot be zero.

The increment added to the force constants, $\Delta \underset{\sim}{\underline{q}}$, after each iteration is calculated indirectly from the following expression

$$
\begin{equation*}
\Delta{\underset{\sim}{\Phi}}^{r}=-\left({\underset{\sim}{D}}^{r}\right)^{-1} \underset{\sim}{g} \tag{23}
\end{equation*}
$$

where $D^{r}$ is a Hessian matrix having elements

$$
\begin{equation*}
D_{i j}=\partial^{2} Q / \partial \Phi_{i} \partial \Phi_{j} . \tag{24}
\end{equation*}
$$

The approach used in the Fletcher-Powell method to calculate $\Delta \bar{\sim} \underline{\sim}$ approximates the Hessian matrix $\underset{\sim}{\underset{\sim}{r}}$ at each iteration. Essentially, a positive definite matrix, ${\underset{\sim}{r}}_{\sim}^{r}$, which is initially an identity matrix, is updated at each iteration. ${ }^{4}$

The procedures for approximating $\underset{\sim}{\underline{r}}$ at each iteration are discussed by Fletcher and Powell (22). However, it can be readily seen from Equation (23) that if ${\underset{\sim}{H}}^{1}$ is initially an identity matrix the direction of movement will be along the negative gradient ( $-\frac{\mathrm{r}}{\sim}$ ) as in the method of steepest descent. As $\frac{\mathrm{r}}{\mathbf{r}}$ approached $\underset{\sim}{D} \stackrel{r}{r}$, the Hessian matrix, the direction of movement is different from the path of steepest descent and an approximation to the Hessian in the neighborhood of the optimum is generated. The use of the Hessian, or an approximation to the Hessian, indicates an attempt to use second-order information. The

[^6]method of steepest descent which is utilized by linear least squares techniques, like that of Snyder-Schachtschneider, uses only gradient or first-order information.

To approach $\underset{\underline{\underline{r}}}{\underline{r}}$ a direction vector must be found and a step-size, $\underline{t}_{\underline{m}}$, calculated at each iteration. The latter calculation occurs in three stages. The first estimates the magnitude of $t \underline{m}$, the second determines an interval containing $\underline{\underline{\underline{m}}}$, and the third cubically interpolates the value of $\underline{\underline{\underline{m}}}$.

The Initial Force Constants

There are no decisive methods for selecting an initial set of force constants. At the outset, some modifications in Pitzner's SVQFF were made in anticipation of some differences between the constants describing these two molecular systems. As mentioned previously, the valence bond constants associated with the methylene atomic groupings in the alditols were distinguished from those associated with the methine atomic groupings. In addition, some changes in the off-diagonal bendbend interactions were made. Both Snyder, et al. (9) and Pitzner grouped a number of related interaction constants together (i.e., their values were assumed to be similar). In the SVQFF for the alditols, the nearest neighbor bend-bend interaction constants were separated. Distinctions were not, however, made with regard to the atomic groupings associated with the various types of interaction constants.

Pitzner noted that the contribution of the CO stretch-bend interactions to the l,5-AHP force field was a major difference between the force fields of THP and the $1,5-\mathrm{AHP}$ compounds. In view of this observation, a series of trial adjustments were made to those constants associated with the methylene atomic groupings (i.e., the terminal carbon atoms). Independent adjustments to the stretch-bend
and bend-bend interaction constants associated with the skeletal coordinates were made also. In the process of exploring how perturbations to the values of these constants affected the computed frequency distributions, a new set of initial constants evolved. The values of the initial constants used in final refinement are given in Table $V$.

Termination of the Force Constant Refinement

The refinement is terminated if either of the following two conditions are satisfied. The first condition requires that all the corrections to the force constants, $\Delta \Phi_{\underline{i}}$, be less than or equal to an arbitrary constant of 0.0001 . The second condition requires that the ratio of the successive weighted sums of squares of the residuals be greater than a fractional constant of 0.995 . In order to check against premature convergence, the latter condition may be required to be met"several times before actual termination is initiated.

RESULTS

If one of the criteria for convergence is satisfied, the secular equation [i.e., Equation (11)] is solved one last time, as shown in Fig. 9. The final refinement ${ }^{5}$ terminated after 17 perturbations after having satisfied the first condition (i.e., all corrections to the force constants were less than 0.0001 ). In this calculation 128 observed frequencies (from ribitol, xylitol and erythritol) were used to adjust 45 independent force constants. The 17 perturbations consumed approximately $71 / 2$ hours of IBM/44 360 CPU time. Both the initial and final set

[^7]of force constants, and a comparison of the two, are given in Table $V$ along with the estimates of standard error. ${ }^{6}$ The estimated errors must be viewed as upper limits, however, because they are derived from the diagonal elements of the final $H^{\mathrm{r}}$ matrix and only approximate the least squares variance-covariance matrix. The approximation is known to be a poor one unless the number of iterations approaches the number of parameters undergoing adjustment (31).

The vibrational frequencies, the potential energy distributions, and the cartesian displacement coordinates for each molecule have been calculated. The less important data have necessarily been excluded from the text of this thesis but can be generated from the data presented. Since, the cartesian displacement coordinates provide complementary information about the molecular vibrations they are excluded. The potential energy distribution:is defined as the way in which the displacement of each internal coordinate contributes to the potential energy of each normal vibration. The relative contribution of the displaced internal coordinates to the total potential energy associated with each normal coordinate are given in Appendix III. ${ }^{7}$ The fractional contribution of each. force constant, $\Phi_{\underline{k}}$, is also evaluated (see Appendix III). 8 The information derived from these distributions describe the vibrations and formulate the bases for the spectral interpretations given.

[^8]The frequencies calculated from the final set of force constants given in Table V are listed in Table VII and assigned to corresponding experimental frequencies. The average error between the calculated and experimental frequencies is $9.0 \mathrm{~cm}^{-1} .^{9}$ The approximate motions which describe each of the calculated modes are also given in Table VII. The more ambiguous motions are illustrated in Fig. 12. These descriptions are based on the potential distribution: associated with each calculated mode. The dominant internal coordinates and potential constants are given in Table XXXV..

Xyitol

The calculated frequencies, their respective assignments and band interpretations are listed in Table VIII. The average error between the calculated and experimental frequencies is $9.4 \mathrm{~cm}^{-1}$. The dominant internal coordinates and potential constants are given in Table XXXVI.

## Erythritol

The calculated frequencies, their respective assignments and interpretations are tabulated in Table IX. The average error is $9.6 \mathrm{~cm}^{-3}$. The dominant internal coordinates and potential constants are given in Table XXXVII.

TABLE IX (Continued)

INTERPRETATION OF THE VIBRATIONAL SPECTRUM OF ERYTHRITOL

Band Assignment

[^11]D-Arabinitol

The normal modes of D-arabinitol were calculated ${ }^{10}$ using the constants modeled from ribitol, xylitol, and. erythritol without any additional refinement. The calculated frequencies and the approximate motions describing each mode are given in Table X. In Table $X$ both the calculated frequencies of D-arabinitol and the observed frequencies (Raman and IR) of D-arabinitol and D, L-arabinitol are given. The average errors are 7.9 and $9.5 \mathrm{~cm}^{-1}$, respectively. The dominant internal coordinates and potential constants are given in Table XXXVII.

[^13]
## DISCUSSION OF RESULTS

## GENERAL COMMENTS

Three criteria have been used to evaluate the success of the NC analyses:

1. The extent to which the observed spectra and the calculated spectra correlate.
2. The transferability of the SVQFF to related molecular systems.
3. The extent to which the constraints imposed on the analyses are satisfied.

In general, the fit to the experimental frequencies of ribitol, $x y l i t o l$, and erythritol was quite good for molecules as complex as the alditols. As shown in Tables VII-IX, the average errors are $9.0,9.4$, and $9.7 \mathrm{~cm}^{-1}$ for ribitol, xylitol, and erythritol, respectively (this excludes the unassigned OH bands). The overall average error is $9.1 \mathrm{~cm}^{-1}$. The overall average error is slightly higher for the alditols than for the $1,5-\mathrm{AHP}$ compounds ( $6.3 \mathrm{~cm}^{-1}$ ). The fit is, however, comparable to that obtained for the aliphatic ethers (9) (average error $10.4 \mathrm{~cm}^{-1}$ ).

The average error is not the only criterion for judging the quality of the fit. For example, Vasko, et al. ( $\underline{3}, \underline{13}$ ) report an average error of $10.0 \mathrm{~cm}^{-1}$ in comparing their data on the calculated and observed frequencies of the $\alpha-\mathrm{D}-$ glucose molecule. However, between $1400-1250 \mathrm{~cm}^{-1}$ they observe 6 bands and predict 12 , and between $800-600 \mathrm{~cm}^{-1} 7$ bands are observed and only 3 are calculated. Thus, the average error is not always indicative of the extent to which the calculated spectra actually match the observed distribution of bands. Average error depends on the nature of the assignment.

Figure 13 compares the results of the final refinement. Both the calculated and experimentally observed frequencies of each alditol used in the refinement are plotted. In all cases the computed spectra approximate the observed spectra quite well. There are a few experimental bands (usually weak in intensity) which could not be correlated with calculated frequencies. It is suggested that these bands do not represent fundamental modes.

In the spectra of ribitol, for instance, the experimentally observed bands at $2858 \mathrm{~cm}^{-1}(R, I R)^{11}, 695 \mathrm{~cm}^{-1}(R, I R)$, and $575 \mathrm{~cm}^{-1}(R, I R)$ have not been assigned as fundamental modes. These bands do not appear in Fig. 13 but are designated in Table VII. There are also several instances of apparent correlation field splitting of fundamental vibrations (an effect produced by the intermolecular coupling of molecules in the unit cell). These have been designated in Tiable VII and Fig. 13.

The bands at 2858 and $695 \mathrm{~cm}^{-1}$ are suspected of being either overtone or combination bands because of their low intensities in both the Raman and infrared. The $695 \mathrm{~cm}^{-1}$ is poorly resolved in the IR because it appears as a shoulder on the broad band at $624 \mathrm{~cm}^{-1}$. The band at $575 \mathrm{~cm}^{-1}$, though barely visible in the Raman is quite strong in the IR. It is possible that this band is an overtone whose intensity is enhanced as a result of Fermi resonance. Fermi resonance is a phenomenon that may occur when two vibrational energy levels (usually one fundamental and one overtone) have nearly the same energy and are symmetrically suited. In such cases, the intensity of the overtone is enhanced and becomes almost if not equally as strong as the fundamental. In addition,

[^14]Split Band

 | $\circ$ |
| :--- |
| $\square$ |
|  |

the two levels "repel" one another, so that the one with the greater energy moves to a higher frequency, and the one with the lower. energy moves to a lower frequency (32). The $575 \mathrm{~cm}^{-1}$ is located between two fundamentals, one at 624 $\mathrm{cm}^{-1}$ and the other at $529 \mathrm{~cm}^{-1}$.

The situation is similar in the case of xylitol. The observed bands at $695 \mathrm{~cm}^{-1}$ (IR), $563 \mathrm{~cm}^{-1}$ (IR), and $297 \mathrm{~cm}^{-1}$ (R) have not been assigned as fundamentals. Neither of the first two bands are Raman active. The $695 \mathrm{~cm}^{-1}$ band is extremely weak and appears as a poorly resolved shoulder on the strong fundamental at $742 \mathrm{~cm}^{-1}$. The $563 \mathrm{~cm}^{-1}$ band is fairly strong in the IR but is located between two fundamentals, one at $598 \mathrm{~cm}^{-1}$. (IR) and the other at $520 \mathrm{~cm}^{-1}(\mathrm{R}, \mathrm{IR})$. Crystal field splitting of several fundamentals is also suggested and the appropriate bands have been designated in Fig. 13 and in Table VIII. In the erythritol spectra there are no suspected overtone or combination bands. Instances of apparent field splitting are designated in Fig. 13 and Table IX.

Comparison of the calculated and observed distributions in Fig. 13 with these factors in mind, shows that the fit in the case of ribitol is not quite as good as the fit obtained to the spectra of the other two alditols. The fit between the observed and calculated spectra of xylitol is perhaps the best. It is noteworthy that in the case of 1,5 -anhydroribitol (1,5-AHR), studied by Pitzner (1), the correlation between the observed and computed distributions was not nearly as good as the fit obtained between the experimental and calculated modes in the other 1,5-AHP's. Although the average error was $7.6 \mathrm{~cm}^{-1}$ as compared to the overall error of $6.3 \mathrm{~cm}^{-1}$, there were 9 observed bands between 1150 and $650 \mathrm{~cm}^{-1}$ which could not be correlated with calculated modes. However, this does not necessarily suggest a trend.

Careful examination of the observed and calculated spectra plotted in Fig. 13 shows that in each instance there are characteristic gaps in the distribution of the bands between $1500-400 \mathrm{~cm}^{-1}$. Essentiałly the alditol spectra are structured into well-defined groups of bands in this particular region. The first characteristic gap occurs between $1200-1150 \mathrm{~cm}^{-1}$. The potential distributions indicate that this gap is an apparent transition point between valence angle bending coordinates involving at least one hydrogen atom, and skeletal stretching vibrations. Another characteristic void occurs between approximately $850-750 \mathrm{~cm}^{-1}$ in all the spectra. It is widest for erythritol ( $170 \mathrm{~cm}^{-1}$ ) and equal for xylitol and ribitol ( $108 \mathrm{~cm}^{-1}$ ). The potential distributions indicate that above the gap skeletal stretching vibrations dominate while below the gap skeletal bending vibrations predominate.

The calculated distributions do, however, deviate somewhat from the observed distributions below $400 \mathrm{~cm}^{-1}$. The deviation results from the fact that there are more calculated bands than observed bands in each of the spectra. The most logical explanation for this is that the predicted bands simply cannot be resolved. Many of the calculated modes are close to accidentall degeneracy in this region. This may account, in part, for both the larger widths and asymmetric contours of many of the bands in this region. Two additional factors also combine to make band resolution more difficult. First, many of the low energy vibrational bands may be inherently too weak to be observed in either the Raman or IR. Secondly, higher backgrounds interfere with the resolution of the weaker bands. Rayleigh scattering interferes at low wavelengths in the Raman causing the base line to increase sharply in this region. In the infrared KBr absorption begins to occur at about $350 \mathrm{~cm}^{-1}$.

Aside from the fact that both the observed and computed band distributions agree quite well for each of the alditol models, their respective force fields were identical. Thus, the observed differences in the frequencies between the pentitol compounds must result primarily from differences in their G matrices. Unlike the $1,5-\mathrm{AHP}$ 's, the bond angles and bond lengths are not all the same and thus they contribute to the differences in the respective $G$ matrices. However, the dominant structural differences result from both conformational and configurational differences among the isomers in the case of the pentitols. Thus, the frequency variations in their spectra must then be attributed primarily to the changes in the coupling of vibrations that result from these structural differences.

The results also indicate that most of the vibrations in the molecules studied arise, to a first approximation, from the isolated molecule, apart from its environmental surroundings. The fact that a good fit to the observed spectra of erythritol was obtained using the same field substantiates this observation. Erythritol differs from the pentitol models in size, complexity (there are 8 molecules per unit cell as opposed to 4 per unit cell in each of the other alditols), and vibrational degrees of freedom. However, it is important to emphasize that these findings do not necessarily imply that this approximation can be applied to all molecules. They do complement the work of Pitzner (I) and thereby add support to the notion that a key factor in understanding the vibrational spectra of other carbohydratesmolecules, such as the pentoses and hexoses, will depend primarily upon the properties of the isolated molecule treated as a vibrating unit in the crystal lattice.

The sensitivity of the calculated modes to structural differences brought about by changes in the conformation of the molecular model is shown in Fig. 14.

The calculated distribution of frequencies in the spectrum of ribitol between $1500-200 \mathrm{~cm}^{-1}$ is shown in Fig. $14(\mathrm{a})$ as are the distributions calculated from three other conformational isomers of ribitol. In conformation C(I) the ribitol model is in an extended chain conformation similar to erythritol and D-arabinitol. This conformation was formed by a. $120^{\circ}$ rotation (counterclockwise) about $C(3)-C(4)$ which results in a syn-axial interaction between $\mathrm{C}_{2} \mathrm{O}$ and $\mathrm{C}_{4} \mathrm{O}$ (see Fig. 21, Appendix I). No other structural changes were made. Conformation C(II) was formed by a rotation about $C(1)-C(2)$ so that the terminal hydroxyl group on C(I) was in a conformation identical to that of xylitol. The final conformation $C$ (III) was formed by combining the structural changes made to form $C(I)$ and $C(I I)$ ). The frequencies calculated for each of the three isomers are listed in Table XI.

From Fig. 14 and Table XI it is evident that the sensitivity of the bands in the ribitol spectrum to these conformational changes is greatest between $1150-200 \mathrm{~cm}^{-1}$. Comparing the Raman spectrum of ribitol in solution with that of the solid (shown in Fig. 2) indicates that the most significant changes in the distribution of bands occur in this same region. The possible conformations of ribitol in solution are numerous indeed. However, the data presented in Fig. 14 suggest that changes in the distribution of bands in solid-state vibrational spectra which occur upon solution result, in part, from the structural differences among the various conformational isomers. The structural differences among the isomers result in significant changes in the vibrational coupling associated with the fundamental modes.

[^15]The normal modes of D-arabinitol ${ }^{12}$ were calculated for two reasons:

1. To test the predictive capabilities of the force constants calculated using models of ribitol, xylitol, and erythritol.
2. To possibly resolve the uncertainty as to whether the structure of the $D$ isomer in the $D, L$ crystal is the same as its structure in the optically active $D$ isomer.

The calculated frequencies are plotted in Fig. 15 as are the experimental frequencies in the spectra of both $D$ and $D, L$-arabinitol. These frequencies are compared in Table $X$ also. From Fig. 15 it is evident that the calculated frequencies approximate the observed frequencies in both the $D$ and $D, L$ forms quite well. The results suggest that the model force field in Table $V$ is well suited to this class of compounds. The ability to transfer these constants to D-arabinitol suggests that the field does have physical significance, includes sufficient interaction terms, and should provide an adequate approximation to the spectra of other related alditols.

## COMPARISON OF THE D AND D,L-ARABINITOL SPECTRA

As a matter of interest, a racemic mixture of the $D$ and $L$ isomers was prepared. The spectra ( $R$ and IR) of the mixed crystal form were compared with the observed spectra of the D isomer. If the molecular vibrations below $3000^{13}$ were totally independent of the crystalline environment (which was

[^16]
certainly not expected to be the case), then the spectra of the mixed crystal should be identical to either isomer, provided that the molecular conformations remain the same (which is not necessarily the case). Consequently, such a comparison would provide some insight into the effects of the unit cell geometry and intermolecular interactions on vibrational spectra.

A similar comparison was made by Pitzner (1) on 1,5-anhydro-D,I-arabinitol and its L isomer. Pitzner noted that the D,L spectra correlated fairly well with that of the optically activieeL isomer, but that a number of the $D, L$ bands were shifted in frequency from corresponding bands in the spectra of the $L$. isomer. He noted that suspected differences in the geometry of their unit cells and/or differences in the intermolecular hydrogen bonding could possibly explain the differences in the spectra of the two forms.

From Fig. 7 and 8 it is apparent that differences do occur between the spectra of the $D, L$ mixed crystal and the optically active $D$ isomer of arabinitol. These differences have been classified into 5 types:

1. Differences in the frequencies of the observed fundamentals.
2. Differences in the relative intensities of the observed bands.
3. Differences relating to the Raman or IR activity of the fundamental modes.
4. Apparent differences in the number of suspected overtone or combination bands.
5. Apparent differences in the number of vibrational splitting effects (correlation field splitting).

In Table $X$ the computed frequencies of D-arabinitol were correlated with the experimentally observed bands in the spectra of both the $D$ and $D$, forms. An element of trial remains in these correlations and their validity must in part be judged on the basis of all the results obtained from the NC analyses.

However, using these calculated frequencies an interpretation of the arabinitol spectra was made.

Based on the assignments made in Table $X$ it was possible to compare the observed bands in the arabinitol spectra. It is evident that a number of bands in the $D$ spectra are shifted in frequency from similar bands in the $D_{2} L$ spectra. These shifts result in noticeable changes in the distribution of observed bands in Fig. 15. However, judging from the data presented in Table $X$ and the distributions plotted in Fig. 15 , the changes in the distributions are not comparable to the types of differences that occur among the pentitol spectra. Comparing the arabinitol spectra, there are, in fact, only 5 assigned bands in the Raman spectrum of the $D$ isomer $(1440,1357,697,363,295)$ that differ in frequency by more than $10 \mathrm{~cm}^{-1}$ from corresponding bands in the $D, L$ mixed crystal. Of these 5 bands, two differ in frequency by only $11 \mathrm{~cm}^{-1}$ and none differ by more than $15 \mathrm{~cm}^{-1}$. Furthermore, of the 41 bands compared between 2980 and 300 , only 16 of the observed bands differ by more than $7 \mathrm{~cm}^{-1}$.

The shifts in some of these frequencies are large enough to suggest that there may be minor conformational differences in the terminal methylene hydroxyl groups in the structure of the isolated D isomer. However, no major differences in conformation are indicated. In the case of ribitol, altering the conformation of the molecular model substantially affected the distribution of bands in the calculated spectrum. Comparatively large shifts in the band distributions occurred between 1030-350 (see Fig. 14 and Table XI). Skeletal stretching and bending modes are active in this region indicating that the coupling of vibrations involving the carbon and oxygen atoms are especially sensitive to structure. Relatively minor differences between the arabinitol spectra occur in this region. Thus, these shifts are suggested to result from either changes in the pattern
of intermolecular bonding between the two crystalline forms, or minor conformational differences.

There are four other types of observed differences that are also significant. First, there are major differences in the band intensities. For example, the relative intensities of the D-arabinitol bands between 1400-1200 and between 400-200 indicate that these bands are more intense than corresponding $D, I$ bands. Intensity variations usually indicate changes in the nature of the bond. Variations in intermolecular bonding can influence band intensities, and therefore it is significant to note that the melting point of the $\mathrm{D}, \mathrm{L}$ form $\left(105^{\circ} \mathrm{C}\right.$ ) is 14.5 degrees higher than the D isomer. However, other factors are involved. For example, the $D$ isomer is optically active, whereas the racemic mixture is not. Optical activity may influence the intensities. The consequences of optical activity, if any, on vibrational spectra have not been explored. Also, unit cell geometry may again be a factor. Because the unit cell of the $D, L$ mixed crystal is different than that of the $D$ isomer, differences in the intensity of the scattering may result.

Secondly, though most every band in the $D$ isomer is active in both the Raman and IR there are a few instances in the D,L spectra where mutual activity is not observed. However, in view of the weaker intensities of many of the bands in the D, L spectra the bands not observed may be inherently too weak for detection. For example, there are 7 bands between 2980 and 400 [2966(R), 1465 (IR), 1425(IR), $1312(\mathrm{IR}), 1271(\mathrm{R}), 1230(\mathrm{R})$ and $1115(\mathrm{R}) \mathrm{l}$ in D,L-arabinitol that are not mutually active. The 1425 (IR) band is a broad, poorly resolved band of medium intensity. Corresponding bands (see Table $X$ ) in the spectra of the D isomer occur at $1440(\mathrm{~s}, \mathrm{~b})(\mathrm{IR})$ and $1440(\mathrm{w}, \mathrm{sh})(\mathrm{R})$. Judging from the relative IR intensities of these modes, it is likely that the 1425 (IR) band is too
weak to be detected in the Raman spectrum of $D, L$-arabinitol. The same is true for the bands at $2966(R), 1271(R), 1230(R)$ and $1115(R)$ except that they are too weak for IR detection. Poor resolution may be responsible for the fact that the 1465 band is not observed in the Raman.

However, it is also possible that the mutual exclusion observed for these bands is related to the localized inversion symmetry of the $D, L$ pairs in the crystal. When the $D$ and $L$ enantiomers crystallize, $D, L$ pairs are formed and the $D$ enantiomer is hydrogen bonded to the $L$ enantiomer by bonds at two locations. If special selection rules resulting from the inversion symmetry, are. in operation, the breakdown due to anharmonicity is extensive. The majority of the bands in the D,L spectra are mutually active.

There is also a difference in the number of suspected overtone and combination bands in the spectra of the $D$ isomer. The suspected overtone and combination bands are described in Table XII for both crystal forms. As noted above, the relative intensities of the bands between 1400-1200 and 400-200 in the $D$ isomer were more intense than corresponding bands in the spectrum of the racemic mixture. This may account, in part, for the greater number of overtone and combination bands.

For example, in Fig. 7 there is a band at approximately 780 in both spectra. The band is more intense in D-arabinitol than in D, L-arabinitol. Clearly, no fundamentals are predicted to occur in this region. It is therefore suggested that this band is a combination band rather than a fundamental. As specified in Table XII, the suggested combination is $491(\mathrm{~s})+295(\mathrm{~s})=786$ $\mathrm{cm}^{-1}$. A comparison of the relative intensities of the Raman bands at approximately 295 in both spectra (see Fig. 7) reveals that the band is much more intense in the spectrum of D-arabinitol. Thus, a combination of the type suggested would likely be more intense in the $D$ spectrum.

TABLE XII SUSPECTED COMBINATION OR OVERTONE BANDS

| Crystal | Obs. Freq. $\mathrm{cm}^{-1}$ |  |  |
| :---: | :---: | :---: | :---: |
| D-Arabinitol | 2990(w,sh) | $(R)^{\text {a }}$ | $2(1494)(s)=2988$ |
| D-Arabinitol | 1395 (vw, b ) | (R) (IR) | $887(\mathrm{vs})+528(\mathrm{~m})=1415$ |
| D,L-Arabinitol | 1395(w,sh) | (IR) |  |
| D-Arabinitol | 1069(w) | $(\mathrm{R})(\mathrm{IR})$ | $697(\mathrm{~m})+363(\mathrm{~m})=1060$ |
| D-Arabinitol | 909 (w) | $(R)(I R)$ | $3(295)(\mathrm{s})=885$ |
| D-Arabinitol | 782 (m) | (R) (IR) | $295(s)+491(s)=786$ |
| D,L-Arabinitol | 782 (vw) | $(R)(I R)$ |  |
| D-Arabinitol | 736(w, b ) | $(\mathrm{R})(\mathrm{IR})$ | $2(363)(\mathrm{m})=726$ |
| D-Arabinitol | 595 (vVw) | $(\mathrm{R})(\mathrm{IR})$ | $2(295)(s)=590$ |
| D-Arabinitol | 540 (vw) | (R) (IR) | $2(268)(\mathrm{cal})=$. |
| D,L-Arabinitol | 540 (w,sh) | (R) (IR) |  |
| D-Arabintiol | 405 (vvw) | (R) (IR) | $2(196)(\mathrm{cal})=$. |
| D,I-Arabinitol | 406(vw) | (R) |  |

[^17]Another seemingly new band appears at 909 in the $D$ spectrum. In view of the difference in the relative intensity of the 295 band in the Raman spectrum of the $D$ isomer, there is reason to suspect that the 909 band.is a possible overtone [i.e., $3(295)=885 \mathrm{~cm}^{-1}$ ]. The second overtone of this band is also súspected to be Raman active and to occur at 600, though its intensity is much weaker. Although it is unusual for a third overtone to be greater than a second overtone, Fermi resonance could explain the difference. The 909 band is very near a series of fundamental modes which are the strongest bands observed in the spectrum below 1500. The remaining bands suggested to be either overtones or combination bands in Table XII are all relatively weak and located near fundamental modes.

To suggest that the bands given in Table XII are, in fact, overtones and combinations of fundamental bands is done with reservation. There is no direct way to substantiate such an interpretation. It is also possible that a number of these bands result from external vibrations, coupling between external and internal modes (which would also result in combination bands of a summation or difference nature), or thermally excited second-order transitions of low energy fundamentals. Sherwood (33) notes that internal and thermally excited external vibrational coupling become especially important as the vibrations of internal and external modes approach one another in value (i.e., below $800 \mathrm{~cm}^{-1}$ ).

Finally, the perturbations to vibrational coupling by the presence of other molecules in the same unit cell are apparently more extensive in the $D$ isomer as evidenced by the degree of vibrational splitting in the solid state. It should be emphasized that solid-state, splittings or changes in selection rules result from an interaction of a molecule with its environment. In organic substances the most common cause of solid-state effects is hydrogen bonding. Therefore, it is interesting to note that the melting point of the $D$ isomer is 14.5 degrees lower than the $D, L$ mixed crystal. However, factors other than the degree of hydrogen bonding are involved. The coupling together of the vibrations of different molecules within the unit cell may give vibrations which are symmetric or antisymmetric with respect to operations of the crystallographic point group (which is unknown in the case of the $D$ isomer): Consequently, selection, rules would then be an important factor. Although hydrogen bonding would be. expected to be the most common type of intermolecular coupling, electronic coupling is also. possible. As Gans (32) points out, the interactions of molecules in a unit cell are very poorly understood and not amenable to quantitative work, except in the simplest cases.

Apparent correlation field splitting occurs in several regions in both sets of spectra. Between $900-850$ there are clearly four bands ( $887,878,867$, and 855 ) in the D isomer. In the $\mathrm{D}, \mathrm{L}$ spectrum only two bands occur in this region, which is consistent with both the calculated distribution in Table $X$ and the observed distribution in the spectra of its configurational relatives ribitol and xylitol. Also based on the predicted band distributions it is likely that the doublets in the D isomer assigned to the calculated fundamentals at 2934, 1082, 1070, and 938 result from field splitting effects. In the $D, L$ spectrum the corresponding bands assigned to the predicted fundamentals at 2934 and 938 are not split. However, the bands assigned to $1082,1070,1019$ and 718 are split as Table X indicates.

## INTERPRETATION OF THE ALDITOL SPECTRA

The third criterion used in this study to evaluate the quality of the NC analyses related to the extent to which the constraints on the analyses were satisfied. One important constraint stipulated that the interpretations based on the normal coordinates be consistent with the group frequency correlation charts for those regions of the spectra where the charts are applicable.

Unfortunately, the information based on group frequency correlations is of little value below $1500 \mathrm{~cm}^{-1}$. At best, parallels can be drawn between group frequency charts and the calculated frequency of the major components of the normal coordinate associated with each fundamental.

The individual bands in the alditol spectra are best described by the dominant internal coordinates and potential constants associated with each mode (see Appendix III). Though discussion of the individual bands would be beneficial, it would also be impractical due to the number of bands involved
and the complexity of the normal coordinates. However, it is possible to examine the spectra in terms of the group motions described in Tables VII-X. These motions, illustrated in Fig. 12, have been used to approximately characterize the normal coordinate of each fundamental vibration. In. Table XIII, the calculated spectra of the alditols, 1,5-AHP's (1) and the n-paraffins (I) have been compared. The basic group vibrations have been classified in terms of the calculated normal frequencies. Table XIV is constructed similarly to compare each of the alditols in terms of their respective group motions.

The advantages of using group motions to interpret the spectral bands is that the various internal modes may be classified according to frequency. Thus, it is easier to identify trends among the spectra. It must be emphasized, however, that the vibrations of the atoms may be localized within particular atomic groupings. A band interpreted as a methine op bending mode, for instance, can involve a displacement of each of the methine CCH coordinates, although the relative amplitudes of the atoms involved are not necessarily the same.

OH AND CH STRETCHING MODES

The bands in only two regions of the spectrum can be associated with individual group motions. In the first region, between 3350-3100, hydroxyl. ... groups are involved. As Table XIII shows, the OH stretching vibrations were calculated to occur between 3350-3300. The observed OH stretching frequencies, which are clearly sensitive to hydrogen bonding, occurred between 3350-3225. Because these vibrations are not coupled significantly with the vibrations of other groups, they are essentially independent of the rest of the bands in the spectra and were treated accordingly. No attempts were made to correlate the observed and calculated frequencies, and they were excluded from the refinement of the force constant parameters.

The CH stretching modes which were observed between $3000-2800$ constitute the second group of localized vibrations. As Table XIII shows, the bands occur in three distinct groups: asymmetric methylene stretching, methine stretching, and symmetric methylene stretching. This pattern suggested by the potential energy distributions occurs in both the alditols and the 1 , 5 AHP's.

From Table XIV it is apparent that below 1500 the alditol spectra are less structured due to the coupling of vibrations associated with different group motions. Nonetheless, patterns do emerge. The region between 1500-1200 is characterized, in part, by angle bending coordinates involving at least one hydrogen atom. In contrast, bands between 1150-800 are dominated by skeletal stretching vibrations (both CC and $C O$ ), coupled with bending contributions from methylene $\left(\mathrm{CH}_{2}\right)$ and COH groups. Between $800-450$ the majority of bands are characterized by angle bending coordinates not involving hydrogen atoms. Skeletal bending and $C C O$ bending vibrations predominate in this region. Below $450 \mathrm{~cm}^{-1}$ skeletal bending, skeletal torsion, and $O H$ op bending modes contribute significantly as shown in Table XIV. The dominant group motions in each of these regions will be discussed individually beginning with the methylene $\mathrm{CH}_{2}$ bending vibrations.

## $\mathrm{CH}_{2}$ BENDING FREQUENCIES

From Table XIII it is apparent that parallels can be drawn among the spectra of the alditols, $1,5-\mathrm{AHP}^{\prime} \mathrm{s}$, and the n -paraffins. In each class of compounds, the common group vibrations are located in similar regions of the spectrum. Figure 16 represents a diagrammatic summary of the likely frequency ranges of various types of vibrations in polymethylene compounds. The information in Fig. 16 is based on a discussion of the spectra of the planar
zigzag polymethylene-type compounds by sheppard (34). For the most part, the interpreted frequency ranges are based on group frequency correlations among the spectra of related molecules. The dashed lines represent regions where the assignments are the most ambiguous.
$\mathrm{CH}_{2}$ bending

Figure 16. Frequency Ranges of Various Types of Vibrations in Polymethylene Compounds

It is apparent from Table XIII that the calculated distribution of $\mathrm{CH}_{2}$ bending motions in the n-paraffins accurately match the distribution patterns shown in Fig. 16. Figure 16 suggests that the methylene ip (scissoring) bending modes are pure vibrations (i.e., uncoupled) and occur exclusively between 1480-1440 in polymethylene compounds. The distribution of bands associated with methylene op bending (wag and twist) overlap and are suggested to occur between 1450-1150. The bands associated with asymmetric methylene ip bending (rock), shown to have the widest distribution, occur between ll 70-720. However, Fig. 16 does not indicate the extent to which these group motions are coupled.

Schachtschneider and Snyder (I) found that the various $\mathrm{CH}_{2}$ vibrations do couple. In particular, the potential distributions associated with the $\mathrm{CH}_{2}$ wagging modes indicated that these vibrations were coupled to other methylene bending vibrations and to CC stretching vibrations as well. Similar coupling
patterns for these vibrations are predicted for both the alditols and 1,5-AHP's. However, in both cases the coupling is more extensive. In the alditols, for example, methine CH ip and op bending and OH ip bending are substantially coupled to the $\mathrm{CH}_{2}$ deformations which occur between 1400 and 1200. To further complicate matters, both $C O$ and CC stretching vibrations are found to couple somewhat with these vibrations. In all cases, however, the angle bending vibrations involving at least one hydrogen atom predominate in this region. METHINE CH BENDING

The methine CH angle bending vibrations contribute to the potential distribution most heavily between 1450-1200 in the alditols and between 1435-1200 in the 1,5-AHP's as shown in Table XIII. For the most part these methine deformations are confined to this relatively narrow region as both Tables XIII and XIV indicate.

COH BENDING

The COH ip bending vibrations are calculated to couple extensively to group motions between $1450-800$ as shown in Table XIV. To help support the assignments and interpretations based on the NC analyses, the deuterated spectra of ribitol, xylitol, and erythritol were measured. The fundamentals predrioted to have substantial OH ip bending contribution were expected to be affected by deuterium substitution.

Five kinds of changes in the spectra of these compounds were observed after deuterium exchange with the hydroxyls:

1. Bands disappeared completely.
2. The relative intensities of bands were reduced, but the bands did not disappear.
3. The relative intensities of bands increased.
4. The frequencies of a number of bands shifted to higher or lower levels.
5. New bands appeared.

A mode is considered to be characteristic whenever it corresponds to a vibration of a particular type of bond or bond angle. Therefore, when a characteristic COH frequency decreases in intensity upon deuteration; a COD mode should be observed at a lower frequency in the spectrum. The first and fifth kinds of observed changes, mentioned above, exhibit this type of behavior. Bands that disappear upon deuteration can readily be associated with 0Hfrelated vibrations. However, new bands which appear in the spectra upon deuteration cannot always be associated with COD related vibrations. This point will be discussed in greater detail later. Intensity changes are difficult to interpret as are the observed shifts in frequency. These effects are undoubtedly related to changes in the nature of both the bonds and the vibrational coupling. The fact that change does occur, however, is sufficient to establish the contribution of the hydroxyl ppoton to the overall motion.

In ribitol, for example, displacement of COH coordinates contribute substantially to the potential associated with the following calculated frequencies: $1426,1331,1312,1295,1292,1268,1265,1252,1231,1213$, and 1202 (see Table VII). In each instance the observed bands assigned to these frequencies are affected by deuteration. The observed Raman bands assigned to fundamentals at $1426,1312,1231$, and 1213 disappear completely with deuteration. Furthermore, the relative intensities of the two bands assigned to frequencies 1268 and 1265 are considerably reduced. At 1268 the methylene COH contribution is approximately $53 \%$, and $47 \%$ at 1265 (see Table XXXIV). In most other instances the coupling of COH vibrations is such that this kind of characterization is
not possible. The results from deuteration studies on other aliphatic hydroxy compounds support the likelihood of this assignment (35). In l-propanol methylene, OH bending occurs at 1275, in ethylene glycol at 1274, in glycerol at 1268 , and in diethylene glycol at 1283 and 1267. In glucose (13) the mode most often assigned to the $\mathrm{CH}_{2} \mathrm{OH}$ group occurs at 1278 . The observed bands at $1295(\mathrm{~m}, \mathrm{sh})$ and $1289(\mathrm{~m})$ assigned to 1295 (calc.) and 1292 (calc.), respectively, are shifted in frequency somewhat and their relative intensities increase. The remaining two bands in this group, assigned to frequencies 1331 and 1202, are low intensity bands observed in the IR only. Infrared spectra on deuterated samples were not utilized in most cases (erythritol is the exception) due to the poor resolution obtained and the difficulty caused by $\mathrm{H}_{2} \mathrm{O}$ contamination during pellet formation.

In the next region between $1200-800$, which is dominated mostly by CC and CO stretching vibrations, assignment of COH frequencies by isotopic substitution is especially difficult. The spectral resolution is complicated by a number of factors. First, the bands are noticeably broader (see Fig. 17). Some lines decrease: in intensity but do not disappear, and the presence of additional bands in the spectra begin to interfere with existing bands. Furthermore, even though repeated crystallization from the deuterated solvent improves the degree of deuteration, complete (i.e., $100 \%$ ) exchange is unlikely. Consequently, the observed spectrum in Fig, l represents a superposition of the scattering from both ribitol and deuterated ribitol. Because substantial changes are observed it is very difficult to directly correlate the bands in the ribitol spectrum with bands in the spectrum of the isotopically substituted sample. In spite of these difficulties, the effects observed upon deuteration are reasonably consistent with the predicted coupling of OH ip vibrations with the skeletal stretching modes.

Figure 17. Raman. Spectra of Ribitol

For example, in Fig. 17 the Raman bands observed at 1135 and 1118 are shifted slightly in frequency and the intense 1054 band disappears. This latter band which is assigned to the calculated fundamental at 1047 shows substantial OH bending contribution to the associated normal coordinate. The band at 1093 is not present in the deuterated spectrum, but may well be hidden in the background. The bands at 1037 and 948 disappear completely. The intensity of the 915 band is reduced, a shoulder appears on the band at 893 , and the 864 band has apparently shifted to 828 (a change of $56 \mathrm{~cm}^{-1}$ ). In addition, at least 3 new bands (1185, 1161, 1144) appear in the void characteristic of the pentitols
between 1200 and 1150. The band at 1161 is particularly strong. Two other new bands appear in the deuterated spectrum also, one at 1023 and the other at 994.

The xylitol spectra are similarly structured with respect to COH ip vibrations. Table XIV shows that COH vibrations are predicted to be most active in two regions between 1330-1200 and between lll5-850. From Fig. 4, however, it is apparent that the xylitol bands between 1410 and 1381 are affected by isotopic substitution. For example, the observed band at 1407 , which is assigned to the calculated fundamental at 1396, disappears. The associated normal coordinate shows that the principal motions are the methine and methylene CH and COH bending vibrations. Though resolution in the xylitol spectrum is extremely poor between 1380 and 1335, three bands have been identified at $1374(\mathrm{w}, \mathrm{sh}), 1352(\mathrm{vw}, \mathrm{b})$, and $1346(\mathrm{w}, \mathrm{sh})$ and are assigned to 1362,1355 , and 1347 , respectively. The intensities of these bands are affected by deuteration as shown in Fig. 4. Of the three bands, the bend assigned to 1355 shows a $15 \% \mathrm{COH}$ bending contribution as compared to $5 \%$ for the 1362 band. As predicted, deuteration confirms that all the normal modes between $1330-1200$ involve substantial contribution from coupled COH ip bending vibrations. Characteristically, the methylene COH bending vibrations occur at 1297 and 1274.

Between 1200 and 800 the skeletal stretches show significant coupling with COH bending vibrations. Though resolution is even more of a problem in xylitol than in ribitol, the relative intensities of the bands assigned to ll09, 1059, 928, and 893 are all reduced, which is consistent with the extensive coupling of CO stretch and COH bending motions predicted by the potential distributions of these modes. New bands appear in the deuterated spectrum at 1176 (w), $1157(\mathrm{w}, \mathrm{sh}), 1137(\mathrm{~s}), 1120(\mathrm{~m}), 1040(\mathrm{sh}), 942(\mathrm{vw}), 930(\mathrm{vw}), 905(\mathrm{sh})$ and $880(\mathrm{vw})$. Frequency shifts and intensity changes occur also. The band assigned to 1029
which is initially very weak in the Raman increases substantially upon deuteration. Furthermore, the band observed at 858 (vs) apparently shifts to 840 , though the relative intensity is essentially unchanged.

In erythritol, bending motions involving hydroxyl protons are similarly distributed. The relative intensities of the bends observed at lit56(s) and . 1366(m) increased after deuteration as shown in Fig. 18.

Wave Numbers, $\mathrm{cm}^{-1}$
Figure 18. Infrared Spectra of Erythritol
(A) Solid; (B) Deuterated

The 1456(s) band, primarily a methylene HCH bending mode; is assigned to the mode calculated at 1457 and shows an $8 \%$ methylene COH ip bending contribution. Methylene wag ( $21 \%$ ) and COH ip bending ( $24 \%$ ) both contribute to the 1366 mode. Methine and methylene COH ip bending characteristically occurs at 1276 (calc.) and l250(calc.) also. The relative intensities of the bands assigned to these fundamentals are significantly reduced after deuteration. Another
band at 1375, which is observed in Fig. 18 as a shoulder on the 1366(s) band, disappears and the bands at 1216 and 1053 are reduced in relative intensity. New bands appear at 1115,1008 , and 820 , and the majority of bands between 980800 are all significantly shifted in frequency.

Prom the above discussion it is clear that the bands assigned to fundamentals involving $O H$ ip bending vibrations are affected by deuteration. Both the experimental and calculated data indicate that $C O H$ ip bending motions are coupled substantially with other group vibrations having a broad distribution of frequencies. Furthermore, the structure of the alditol spectra with respect to COH related motions is reasonably consistent with the structure of the spectra of the aliphatic hydroxy compounds mentioned earlier (i.e., l-propanol, ethylene glycol, glycerol, and diethylene glycol). The fact that a reasonably good fit to the observed spectra was obtained in spite of the extensive coupling of OH ip motions with skeletal stretching modes suggests that the effects of hydrogen bonding are not transmitted to the skeletal vibrations.

In view of the correlation between the bands affected by deuteration and the bands calculated to have a substantial $O H$ ip bending component, a calculation of the frequencies of deuterium-substituted ribitol and xylitol was undertaken. The hydroxyl protons in each molecule were replaced with deuterium by making the appropriate changes in mass and constructing a new $\mathcal{G}$ matrix for each compound. When an atom of a molecule is replaced by an isotopic atom of the same element, it is assumed that the changes in the potential energy function and configuration of the molecule are negligible ${ }^{14}$. Consequently,

[^18]the force constants are unaffected. However, the frequency parameters, $\lambda_{\underline{k}}$, are affected substantially as a result of the changes in both the vibrational coupling and the masses of the hydroxyl protons. Vibrational frequencies involving hydrogen atoms oscillating with large relative amplitudes will be affected more than frequencies where the hydrogen atoms are vibrating with small relative amplitudes. In the limiting case where only hydrogen atoms are moving, a replacement of all of them by deuterium should decrease the corresponding fundamentals by a factor of $1 / \sqrt{2}$ (i.e., the reciprocal of the square root of the ratio of the masses).

Table XV compares the observed Raman spectrum of deuterated ribitol with the computed spectra of both ribitol and deuterated ribitol in the frequency range from $3400-600 \mathrm{~cm}^{-1}$. ${ }^{15}$ A similar comparison of the xylitol spectra is given in Table XVI.

In both cases the predicted shifts in the OH stretching frequencies correlate very well with the observed shifts. The bands with normal coordinates possessing substantial $C O D$ ip bending are calculated to occur between 840 and $600 \mathrm{~cm}^{-1}$. Many of the new bands observed in the deuterated spectra occur between 940 and $840 \mathrm{~cm}^{-1}$. Thus, it is apparent that the predicted shifts are somewhat lower than the observed shifts. However, an exact correlation was not anticipated. Whereas the OH stretching vibrations involve primarily the hydroxyl protons, the OH bending vibrations are extensively coupled. The extent of shifting will depend on the exact form of the normal coordinate (i.e., the exact nature of the coupling). Clearly, the results from the NC analyses can only approximate the nature of the coupling. Further scre.

[^19]TABLE XV
CALCULATED AND OBSERVED SPECTRA OF DEUTERIUM SUBSTITUTED RIBITOL

discrepancies in the shifting result from the fact that the observed frequencies are influenced by cubic and quartic terms in the potential energy. The effects of hydrogen bonding also perturb the coupling of these vibrations with other group motions.

In spite of the observed discrepancies, the trends between the calculated and observed data in Tables XV and XVI are revealing. For example, one of the most important differences in the spectra of the deuterated pentitols was the appearance of a series of bands between $1200-1140 \mathrm{~cm}^{-1}$. No bands are observed in this region in the spectra of the unsubstituted alditols. However, the calculations in Tables XV and XVI show that the agreement between the calculated and observed spectra of the deuterated pentitols is quite good in this region. In fact, if one allows for the fact that some proton exchange occurred during sample preparation, the correlation between the deuterated spectra and the calculated spectra of both the substituted and unsubstituted pentitols is very good between 1185-975 $\mathrm{cm}^{-1}$. The potential distributions associated with the bands calculated between $1200-1140 \mathrm{~cm}^{-1}$ indicate that these "new" bands are not COD related vibrations. They are, in fact, predominately skeletal stretching vibrations which exhibit very little (less than $10 \%$ ) coupling with COD components. Consequently, "new" bands which appear in the vibrational spectra after deuteration cannot necessarily be correlated with COD related vibrations. The calculated distributions do indicate, however, that the new bands which occur between $900-800 \mathrm{~cm}^{-1}$ are likely to be COD related vibrations. The weak intensity of these bands relative to the bands between $1200-1100 \mathrm{~cm}^{-1}$ suggests that it is also quite possible that some of the $C O D$ bands may be inherently too weak for detection.

In the alditols, it is apparent from Table XIV that between $1150-800$ extensive coupling occurs among the skeletal stretching, OH ip bending, and methylene twisting and rocking vibrations. The presence of the skeletal CC and CO stretching components in this region is consistent with the interpretive trends based on group frequency correlations. In Fig. 16, for instance, the $\mathrm{CH}_{2}$ rock and CC stretching bands are shown to overlap extensively. However, overlapping of the bands does not necessarily imply coupling of the internal modes. Snyder and Schachtschneider (8) found the coupling of the CC stretch, methylene rock, and methylene twist to be extensive: In the case of the n-paraffins the coupling is also influenced by the methyl rocking modes in this region. For example, in $\underline{n}$-pentane (gauche) the calculated fundamental at 1107 contained the following components: methyl rock ( $32 \%$ ), CC stretch ( $24 \%$ ), methylene twist ( $17 \%$ ), and methylene rock ( $14 \%$ ). Figure 16 suggests that methylene twisting and rocking appear in two regions, the twisting between 1311-1170 and the rocking between 1061-721. In contrast, Schachtr: schneider and Snyder (I) found that methylene rocking and twisting components: are coupled in both regions to each other and to methyl rocking and skeletal stretching components as well.

In spite of the extensive coupling in this region the bands in the alditol spectra are for the most part characterized by CC and CO stretching vibrations. An analogous situation occurs in the spectra of the l,5-AHP's where a number of vibrations in this region involve ring stretching vibrations (1).

The mixing of the CC and CO stretching components, which is clearly evident from the potential distributions in Appendix III, shows the result
of having similar bonds and similar masses in a chainlike molecule. In a carbon chain molecule there will not be one characteristic CC frequency. Coupling will occur between the equivalent bonds which leads to a splitting of the characteristic frequency. The stronger the coupling between these bonds, the larger the splitting, and the wider the frequency distribution. The CC and CO force constants are of similar magnitude and the masses of the carbon and of oxygen atoms are comparable. Thus, the vibrations of the atoms in these atomic groupings would be expected to be highly mixed. For example, in paraffin molecules the CC stretching viibrations often give weak bands in the IR because the changes in the dipole moments associated with these bonds are relatively small. However, in molecules such as the straight-chain alcohols, the intensity of the various skeletal bands is greater. The coupling of the more polar $C O$ bond with the $C C$ stretching components is the attributed cause of the increase in the relative intensities of these bands (34).

The skeletal vibrations of the alditols encompass the entire $C C$ and $C O$ bond network, and not just the vibrations of the carbon atoms in the backbone. Figure 19 compares the basic structures of $x y l i t o l$ and ribitol with respect to the relative orientations of the carbon and oxygen atoms. These molecules are configurational isomers. The only structural differences occur in the relative orientations of $\mathrm{O}_{13}$ and $\mathrm{O}_{6}$. However, based on geometric considerations, changing the orientation of $O_{13}$ and $O_{6}$ in $x y l i t o l$ is likely to affect the coupling of the skeletal vibrations throughout the entire molecule.

In xylitol there are two intersecting planes that contain a zigzag arrangement of successive $C C$ and $C O$ bonds. The first plane, which contains 6 atoms and 5 successive bonds, is formed by $O_{6}, C_{1}, C_{2}, C_{3}, C_{4}$ and $O_{16}$ shown in Fig. 19. The second contains 5 atoms and 4 successive bonds and is defined
by $O_{13}, C_{3}, C_{4}, C_{5}$, and $O_{19}$. The different orientations of the $O_{13}$ and $O_{6}$ atoms in ribitol reduce both the total number of atoms and successive bonds in each plane by one.

Figure 19. Basic Backbone Structure of Xylitol and Ribitol

There is a strong possibility that the degree of interaction between successive bonds is reduced by the reorientation of these atoms to positions outside either of the intersecting planes. Thus, the manner in which the vibrations in xylitol and in ribitol couple will be markedly different.

It is interesting to note that a similar geometric difference occurs between the $\alpha$ - and $\beta$-glucose molecules which are configurationally different at the anomeric site. The beta form of glucose consists of five similar bond types all lying approximately in an extended, planar, zigzag arrangement across the ring oxygen atom. Only four such bonds exist in the alpha form (see Fig. 20).

Again, from simple geometric considerations the nature of vibrational coupling present in the beta form would be expected to be different than in the alpha form. In both of these instances there is little doubt that other and perhaps even more significant changes in the coupling, which are not envisioned as easily, do occur.

Beta Form

## Alpha Form

Figure 20. Configurations of $\alpha$ - and $\beta$-Glucose

Another aspect concerning the skeletal vibrations deserves to be emphasized also. While the results of the analyses indicate that $C C$ motions couple with the other CC and CO vibrations, the coordinates involved indicate that the vibrations are quite often localized. For example, the intense ribitol band observed at $1078(s)(R)$ has been assigned to the calculated fundamental at 1073 in Table.VII and is iṇterpreted as primarily a CC and CO stretching mode. As indicated in Appendix III, the coordinates involved show that the motion is localized primarily on atomic groups adjacent to $C(2)$ (see Fig. 19). The dominant components in the normal coordinate are: ClC2(17\%), $\mathrm{C} 20(12 \%), \mathrm{COH} 2(24 \%)$, and C4C5(16\%). Likewise in the 1138 band the coordinates involved are: ClC2(25\%), $\mathrm{C} 2 \mathrm{C} 3(22 \%), \mathrm{ClO}(6 \%)$, and $\mathrm{C} 30(5 \%)$. However, there were no perceptible patterns in
the nature of the coupling which could be related to the structural differences among the pentitols. Each fundamental was unique with respect to the components involved. The nature of the coupling suggests that any detailed interpretation of the vibrational spectra of molecules as complex as the alditols must involve analyses of their respective normal coordinates.

## CC STRETCHING MODES IN THE ALDITOLS AND l,5-ANHYDROPENTITOLS

Part of the rationale for studying both the l,5-AHP.'s and the pentitols focused on their obvious geometric differences. Table XIII shows that a difference is predicted in the structure of their spectra with respect to the distribution of CC stretching modes. Ring CC stretching vibrations are predicted to occur between 1160-850 in the l,5-AHP's. Also, they are predicted to couple very heavily with both the ring bending vibrations (or ring breathing modes as they are sometimes called) and CCO bending vibrations which occur in many of the modes between 750-300. The situation is apparently different in the alditols. Although the skeletal stretching and bending components do couple, the contribution of the CC stretching components to the potential distributions associated with the bands in this region is small in comparison. It is suggested that the difference in the coupling is a manifestation of the ring structure. When a side of one angle is deformed within a closed ring structure all angles must necessarily be deformed. Because the ring behaves as a vibrating entity, the closed structure appears to affect the extent of coupling between the stretching and bending components. These calculations involving the pentitols suggest that a factor to be confronted in going from the 1,5-AHP.'s to more complex pyranoses may be in understanding how the additional atomic groups perturb this coupling pattern.

Interpretation of the vibrational spectra of the alditols below $800 \mathrm{~cm}^{-1}$ is complicated by a number of factors. First, few interpretive guidelines exist in this region. Almost every kind of motion not found between 1500-900 has been associated with bands in this lower region. More specifically, this region reportedly contains bending modes of pyranose rings (38) and of CH groups at the asymmetric carbon atoms in pyranose rings ( $\underline{5}, \underline{38}$ ); nonplanar bending vibrations of hydroxyl groups (i.e., OH Op bending) (37); stretching vibrations of hydrogen bonds (39), and below 150, lattice modes have been reported (33). Secondly, many of the low energy vibrational bands have, in general, relatively weak intensities and asymnetric band contours, most likely caused from either overlapping or from solid-state perturbations. Thus, larger measurement errors are expected.

Aside from these factors, however, there are a number of bands in the spectra of the alditols between 800-500 for which there are no corresponding fundamentals. It has been suggested earlier that these bands do not represent fundamental modes. In the initial stages of the analyses the presence of additional bands posed a difficult problem with regard to the actual assignments (i.e., matching calculated and observed frequency distributions). For example, when Pitzner's SVQFF approximation, described in Table V, was initially applied to ribitol, only two bands, one at 729 and the other at 566 , were predicted between 800 and 490 (see Table VI). Actually, five bands are observed in the Raman spectrum at $749,695,628,575$, and 529 . In the IR spectrum of ribitol, bands occur at 692, 624, 574, and 529. Similar situations exist in the spectra of xylitol and erythritol. Pitzner (1) assigned the bands at 873, 776, and 683 in the 1,5-anhydroribitol (1,5-AHR) spectrum to either overtones or combinations.

Because these $1,5-A H R$ bands were either very weak or nonexistent in the Raman his assignment is plausible.

However, the preponderance of bands in this region of the alditol spectra, for which there were no predicted fundamentals, suggested that Pitzner's field was not an adequate first approximation for the compounds in this region. This is understandable in view of the structural differences between these two classes of compounds. Because there is no direct means to determine which, if any, of the bands in this region are fundamentals, the results from a series of refinements, using the FP method, were analyzed. The final assignments appear in Table XVII.

Each refinement was based on a different combination of band assignments in an attempt to improve the overall distribution of frequencies in this region. By comparing the various refinements it was possible to determine which of the unassigned bands in each of the various molecules were most likely to be overtones, combinations, or higher order transitions of low energy fundamentals. Also, because the potential distributions indicated that skeletal CCO and CCC bending vibrations were likely to be dominant in this region, various combinations of appropriate next nearest neighbor interaction constants were introduced. The field was expanded to accommodate 69 SVQFF constants in the refinement. However, in all cases, these additional constants had little affect on the band distribution in this region. As a result, the final field contained only 59 constants and no next nearest neighbor interaction constants.

Table XVII shows that three of the five unassigned bands in ribitol appear to be fundamentals, namely the bands at $749(\mathrm{~s})(\mathrm{R}), 628(\mathrm{~m})(\mathrm{R})$, and $529(s)(R)$, which incidentally are the strongest Raman bands in the group.

TABLE XVII

A COMPARISON OF THE OBSERVED FREQUENCIES AND CALCULATED FREQUENCIES FROM 750 TO $350 \mathrm{CM}^{-1}$

Ribitol

[^20]The other two bands at $695(V v w, b)(R)$ and $575(v v w, b)(R)$ do not appear to be fundamentals. In xylitol, three of the five bands are assigned as fundamentals. In erythritol, all the observed bands in this region appear to be fundamental modes.

Table XIV indicates that the majority of bands between $800-450$ are characterized by CCO bending vibrations and to a lesser extent by skeletal stretching and bending vibrations. Below 450 skeletal bending, skeletal torsion, and OH op bending modes predominate. Some coupling with methine CH and methylene $\mathrm{CH}_{2}$ deformations was noted, but the relative contribution was small in comparison to the dominant vibrational motions (see Tables VII-X).

## A COMPARISON OF CYCLIC AND ACYCLIC FORCE CONSTANTS

As Table V shows, there are no large or unreasonable kinds of force constants. The values of the related constants maintain a high degree of consistency in different systems using similar force field approximations. Also, convergence of the final values fairly close to the initial force constant values further supports the idea that this type of field is well suited to this class of compounds. These properties suggest that the field does have physical significance, includes sufficient interactions, and should be transferable to other alditol molecules such as the hexitols.

However, far more to the point is the fact that using the model field developed for ribitol, xylitol, and erythritol and structural data from a fourth molecule, D-arabinftol, a good approximation of the latter vibrational spectrum was obtained. This type of transferability has not been previously demonstrated. The ability to predict the spectra of other closely related compounds from their structure establishes the physical significance of the
field. This predictive capacity also suggests another potential use, namely, the possibility of determining the $G$ matrix effects responsible for changes in band distributions resulting from suspected modifications in molecular structure.

Even though there are obvious differences between the pentitols and anhydropentitols, similar groupings occur at the $C(2), C(3)$, and $C(4)$ positions. As a general rule, force constants should be transferable (l) between similar molecules or (2) between similar groupings in different molecules (32,40). However, it is extremely difficult to know when the atomic environments are similar enough to expect transferability among the force constants.

Before comparing the force constants and before attempting to assess the extent of transferability between the similar constants, it must be emphasized that the type of model field used for the pentitols is somewhat different and more diversified than the one developed by Pitzner (1) for the 1,5-AHP's. For example, he grouped a number of internal coordinates and their interactions together in the process of defining his field. In several important instances, interactions specific to the ether linkages in the ring were grouped with interactions at other sites in the molecule. He does not, for instance, distinguish between a gauche CCO, CCO angle interaction; a gauche CCO, CCC angle interaction; a gauche CCC, CCC angle interaction; or a gauche CCC,COC angle interaction. Only one constant defines all of these skeletal bend-bend interaction coordinates. More importantly, the value of that constant will be determined by the manner in which the individual interaction constants are grouped. Thus, it is difficult to compare the force constants for the alditols and 1,5-AHP's because they do not share a common basis of development.

Although the difference in the total number of independent parameters does not suggest a very significant difference in the diversity of the two fields, the variation in the atomic groupings of the individual molecule determines the actual number of necessary constants. None of the off-diagonal interaction constants for the alditol molecules are grouped together, and the distinction in the two types of environments associated with the diagonal constants has already been noted.

However, in view of the similarity in the atomic groupings at the $C(2)$, $C(3)$, and C(4) positions, an effort was made to compare the diagonal constants associated with these groupings. The results are given in Table XVIII. In spite of the fact that these constants do not share a common basis of development, the $\Delta \Phi_{a b}$ values show that the methine stretching constants (i.e., no. $2,4,6$, and 8) are nearly equal. The largest deviation occurs between the CO and $O H$ constants. Also, comparing $\Delta \Phi_{a}$ with $\Delta \Phi_{a b}$, in Table XVIII, shows that the degree of difference between the methine and methylene stretching constants within an alditol ( $\Delta \Phi_{\underline{a}}$ ) is nearly equal to the difference between the acyclic and cyclic methine stretching constants ( $\Delta \Phi_{\text {ab }}$ ). Since the difference is small in both instances, this implies (1) that the effects of the methine and methylene environments on these stretching constants are negligible, and (2) that changing from a cyęlic to acyclic environment does not significently affect these constants.

Comparing the $\Delta \Phi_{\text {e }}$ values for valence angle bending shows that the methylene force constants are different from the methine force constants in every case. Furthermore, the $\Delta \Phi_{\underline{a}}$ values are greater than $\Delta \Phi_{a b}$ values in the majority of cases. This suggests that the bending constants which have the greatest environmental similarity are the closest to being transferable.
table XVIII
A COMPARISON OF THE SVQFF DIAGONAL FORCE CONSTANTS FOR THE ALDITOLS WITH THE 1,5-ANHYDROPENYITOLS

The obvious exceptions are the CCO and COH related constants. However, these comparisons are made with reservation in view of the fact that the two fields were defined and developed differently, especially with regard to the various bend-bend interaction constants.

## CONCLUSIONS

The major conclusions of this thesis derive from and are represented by the success of the normal coordinate analyses. The results of the analyses demonstrate that the vibrational spectra of the pentitols and erythritol can be understood in terms of a relatively simple force field. The spectral interpretations developed in the analyses are supported by a number of factors. First, the agreement between the computed and experimental frequency distributions was good. Secondly, the location of the group vibrational motions was consistent with similar calculations on other carbohydrate compounds. Also, the calculated locations of the various group motions parallel the information from group frequency correlations. Finally, the bands assigned to calculated fundamentals involving $O H$ related bending vibrations are shifted by deuteration.

The major differences among the pentitol spectra result primarily from changes in the vibrational coupling caused by the structural differences among the isomers. This suggests that most of the vibrations in the molecules studied arise, to a first approximation, from the isolated molecule, apart from its environmental surroundings. Although interactions among the molecules in the unit cell were detected the effects on the spectra were localized in particular bands. The effects of hydrogen bonding appear to be secondary and are not transmitted to the skeletal stretching vibrations. The overall band distribution is most sensitive to the interactions between the vibrations of the atoms within the molecule.

The vibrational spectra of D,L-arabinitol were presented and compared to the spectra of the $D$ isomer. Differences in the spectra of the two compounds were noted. The nature of these differences suggests that any differences in the conformation of the $D$ isomer in either of these two compounds are minor. As a result, the differences in their observed spectra were attributed to suspected differences in the geometry of their unit cells and/or differences in the intermolecular hydrogen bonding.

The force field developed using ribitol, xylitol, and erythritol was shown to be capable of predicting the vibrational spectrum of D-arabinitol. This type of transferability has not been previously demonstrated. The ability to predict the spectra of other closely related compounds from their structure suggests that the field does have physical significance, includes sufficient interactions, and should be transferable to other alditol molecules such as the hexitols. This predictive capability also suggests another potential use. It should be possible to determine the $\underset{\sim}{G}$ matrix effects. responsible for changes in band distributions resulting from suspected modifications in molecular structure.

## ACKNOWLEDGMENTS

I wish to sincerely thank Dr. Rajai H. Atalla, Chairman of my Advisory Committee, for his continued personal interest, support, and guidance throughout the course of this investigation.

I also wish to gratefully acknowledge the other members of the Committee, Dr. Donald C. Johnson and Dr. Gary A. Baum for helping to create the atmosphere that made this thesis possible.

Many people have contributed both directly and indirectly to the successful completion of this thesis. I am indebted to each of them. In particular, I wish to acknowledge Messrs. F. R. Sweeney, D. E. Beyer, and G. J. Subert for their help in preparing tables and illustrations for this manuscript. I also wish to thank Messrs. J. J. Bachhuber and J. O.. Church for their computer programming assistance.

I am deeply indebted to The Institute of Paper Chemistry for the financial support which made this study possible.

Finally, my most sincere appreciation goes to my wife, Bev, whose faith, patience, encouragement, and assistance made the completion of this investigation possible.

## APPENDIX II

## DATA NECESSARY FOR THE COMPUTATION OF THE F MATRIX

The information reported in this appendix is as follows:
Content Description of Content Page

1. Table XXX Description of Independent Force Constants ..... 156
2. Table XXXI The $\underset{\sim}{Z}$ Matrix for Xylitol ..... 157
3. Table XXXII The Z Matrix for Ribitol ..... 159
4. Table XXXIII The Z Matrix for Erythritol ..... 161
5. Table XXXIV The Z Matrix for D-Arabinitol ..... 163

| $\Phi_{\underline{i} \underline{j}}$ | Coordinate(s) Involved | $\Phi_{\underline{i j} \underline{j}}$ | Coordinate(s) Involved |

## RESULTS OF THE ANALYSES

The information reported in this appendix is as follows:

Content

1. Table XXXV
2. Table XXXVI
3. Table XXXVII
4. Table XXXVIII

Description of Content

Dominant Internal Coordinates and Potential Constants in the Potential Energy Distribution of Ribitol166

Dominant Internal Coordinates and Potential Constants in the Potential Energy Distribution of Xylitol169

Dominant Internal Coordinates and Potential Constants in the Potential Energy Distribution of Erythritol 172

Dominant Internal Coordinates and Potential Constants in the Potential Energy Distribution of D-Arabinttol175

[^0]:    The term carbohydrates, in this context is used to identify the class of compounds which, in addition to the saccharides, includes their derivatives and other related compounds such as the cyclitols.

[^1]:     which is not necessarily the case, and that there are no overtone or combination bands, and no accidental degeneracies.

[^2]:    ${ }^{3}$ Actually the $G$ matrix is the inverse of the kinetic energy matrix, and should not be confused with the kinetic energy of the system, which is a scalar quantity.

[^3]:    ${ }^{a}$ Saturated.
    Conventional symbolism indicating relative intensity: vs = very strong; $\mathrm{s}=$ strong; $\mathrm{m}=$ medium; $\mathrm{w}=$ weak; $\mathrm{v}=$ very; $\mathrm{b}=$ broad; $\mathrm{sh}=$ shoulder.
    Poor resolution.

[^4]:     $\mathrm{s}=$ strong; $\mathrm{m}=$ medium; $\mathrm{w}=$ weak; $\mathrm{v}=$ very; $\mathrm{b}=$ broad; $\mathrm{sh}=$ shoulder. ${ }^{\mathrm{pr}}$ Poor resolution.

[^5]:    ${ }^{a_{1}}$ I.e., the descriptive code for the force constant terms as they appear in the potential energy distributions.
    $b_{\text {The standard error }}$ in the force constants, $\sigma\left(\Phi_{1}\right)$, is estimated from a matrix developed in the refinement which
    approximates the variance-covariance matrix.
    ${ }^{c}$ Values taken from Pitzner (1).
    
    the initial force constants $\left(\Phi^{b}\right): \%$ difference $=\frac{100\left(\Phi^{a}-\Phi^{b}\right)}{\Phi^{a}}$.
    $e_{\text {Not included in the final refinement. }}$
    ${ }^{\mathrm{f}}$ Values taken from Vasko ( 3,13 ).
    ${ }^{\text {GValues }}$ taken from Snyder and Zerbi (9).
    ${ }^{\text {h}}$ Values taken from Snyder and Schachtschneider (8).
    ${ }^{1}$ I.e., the interaction constant applies equally to both methylene and methine atomic groupings.

[^6]:    Where the $\underset{\sim}{H}$ matrix is to be distinguished from the $\underset{\sim}{H}$ in Equation (16).

[^7]:    ${ }^{5}$ The final refinement represents only one of a series of refinements. The success of any refinement was determined by a number of criteria defined by the constraints placed on the refinement process. The three most important constraints were: (1) an improved correlation between the experimental and calculated frequencies; (2) a plausible potential energy distribution; and (3) reasonable changes in the values of the force constant parameters.

[^8]:     ment. The OH constants were not refined. Also interaction constants found to be insensitive to the data were excluded. Error estimates on these latter constants would be meaningless.
    $7_{\text {The }} \%$ contribution $=\underline{L}_{\underline{i k} \underline{F}-\underline{i} \underline{\underline{i}}} / \lambda_{\underline{k}}$.
    $8_{\text {The }} \%$ contribution $=\underline{J Z}_{\underline{i} \underline{j} \underline{\underline{k}}} \underline{\underline{k}}^{-1} / \bar{\lambda}_{\underline{k}}$.

[^9]:    9 The average error (mean deviation) is a term commonly used in the literature to represent the average difference between the calculated and assigned experimental frequencies. The OH stretching frequencies were excluded from the error computation. The Raman frequencies were used whenever possible due to the poor resolution of many of the infrared bands.

[^10]:    ${ }^{2}$ Difference $=$ obs. freq. (Raman) - calc. freq.
    $\mathrm{b}_{\text {Conventional symbolism indicating relative intensity: }} \mathrm{vs}=$ very strong; $\mathrm{s}=$ strong; m = medium; w = weak; $\mathrm{v}=$ very; $\mathrm{b}=$ broad; sh = shoulder.
    ${ }^{c}$ Apparent correlation field splitting; the approximate midpoint between the split bands is used in the difference calculation.
    ${ }^{\mathrm{d}}$ Suspected overtone or combination band.
    ${ }^{\text {D }}$ Deformation denotes a less specific valence angle bend. (Ip $=$ in-plane and $o p=o u t-o f-p l a n e$.

[^11]:    ${ }^{a_{\text {Difference }}}=$ obs. freq. $($ Raman $)-$ calc. freq.
    $\mathrm{b}_{\text {Conventional symbolism indicating relative intensity: } \mathrm{vs}=\text { very strong; } \mathrm{s}=}^{\mathbf{~}=~}$ strong; $m=$ medium; w = weak; $v=$ very; $b=$ broad; sh = shoulder.
    ${ }^{c}$ Apparent correlation field splitting; the approximate midpoint between the split bands is used in the difference calculation.
     op = out-of-plane.)

[^12]:    $\overline{10}$ The calculated frequencies are based on the structure of D-arabinitol as it exists in the $D, L$ mixed crystal (20).

[^13]:    ${ }^{a}$ The calculated frequencies are based on the structural data for D-arabinitol as it exists in the mixed crystal (20).
    $\mathrm{b}_{\text {Difference }}=$ obs. Preq. $($ Raman $)-$ calc. Preq.
    ${ }^{c}$ Conventional symbolism indicating relative intensity: vs $=$ very strong; $s=$ strong; $\mathrm{m}=$ medium; $\mathrm{w}=$ weak; $\mathrm{v}=$ very; $\mathrm{b}=\mathrm{broad} ; \mathrm{sh}=$ shoulder.
    $\mathrm{d}_{\text {Suspected overtone or combination bend. }}$.
    ${ }^{c s}$ Apparent correlation field splitting.
    $e_{\text {Difference calculation }}$ is based on an approximate midpoint between the split bands.
    pr Indicates poor spectral resolution.

[^14]:    $\overline{11}(R, I R)$ denotes that the band is both Raman and infrared active. In such cases, the Raman frequency is given.

[^15]:    ${ }^{\text {a }}$ Based on the crystal structure determined by Kim, et al. (26).

[^16]:    $12_{\text {Recall the }}$ that calculated frequencies are based on the structure of $D-$ arabinitol as it exists in the D, L mixed crystal (20).
    ${ }^{13}$ In the following discussion, the spectral bands will be referred to by their frequencies in wave numbers.

[^17]:    ${ }^{a}(R)=$ Raman active; (IR) $=$ infrared active.

[^18]:    ${ }^{14}$ For evidence supporting this assumption, see Herzberg, G., Spectra of diatomic molecules. 2nd ed. Table 39: New York, Van Nostrand, 1950.

[^19]:    ${ }^{15}$ The calculated frequencies of deuterated ribitol and xylitol are listed in Appendix IV.

[^20]:    ${ }^{a_{\text {Suspected }}}$ correlation field splitting.

[^21]:    ${ }^{8}$ The torsional coordinates were defined for those atoms in the trans position about each bond.
    The torsional coordinates in this group are summed together (inear combination) to avoid the introduction of further redundancies.

[^22]:    The torsional coordinates were defined for those atoms in the trans position about each bond. bithe torsional coordinates in this group are summed together (linear combination) to avoid the introduction of further redundancies.

[^23]:    $a_{\underline{i}}=$ row, $\underline{j}=$ column.

[^24]:    $a_{i}$ and $j$ denote row and column, respectively; $\Phi_{i j}=$ force constant associated with the $\underline{Z}_{i j}$ element.

[^25]:    ${ }^{a_{i} \text { and }} \bar{j}$ denote row and column, respectively; $\Phi_{i \underline{j}}=$ force constant associated

[^26]:    ${ }^{\text {TThe }}$ contributions are relative and may total more than $100 \%$ due to the presence of negative off-diagonal interaction constants.
    The force constants given are described. in Table V.
    ${ }^{c}$ Only the dominant coordinates are given. The individual coordinates for each molecule are coded in the manner described in Tables XIX-XXI.

[^27]:    $a_{\text {The }}$ contributions are relative and may total more than $100 \%$ due to the presence of negative off-diagonal interaction constants.
    The force constants given are described in Table V .
    ${ }^{c}$ Only the dominant coordinates are given. The individual coordinates for each molecule are coded in the manner described in Tables XIX-XXI.

[^28]:     presence of negative off-diagonal interaction constants.
    $\mathrm{b}_{\text {The }}$ force constants given are described in Table V.
    ${ }^{c}$ Only the dominant coordinates are given. The individual coordinates for each molecule are coded in the manner described in Tables XIX-XXI.

[^29]:    $a_{\text {The contributions are }}$ relative and may total more than $100 \%$ due to the presence of negative off-diagonal interaction constants.
    $\mathrm{b}_{\text {The force }}$ constants given are described in Table V .
    ${ }^{c}$ Only the dominant coordinates are given. The individual coordinates for each molecule are coded in the manner described in Tables XIX-XXI.
