Abstract

We present a new technique for the parallel simulation of cache coherent shared memory multiprocessors. Our technique is based on the fact that the functional correctness of the simulation can be decoupled from its timing correctness. Thus in our simulations we can exploit as much parallelism as is available in the application without being constrained by conservative scheduling mechanisms that might limit the available parallelism in order to guarantee the timing correctness of the simulation. Further, application specific details (which can be gleaned from the compiler) such as data layout in the caches of the target architecture can be exploited to reduce the overhead of the simulation. The simulation correctness is guaranteed by patching the performance related timing information at specific points in the program (commensurate with the programming model). There are two principal advantages to this technique: being able to simulate larger parallel systems (both problem size and number of processors) than is feasible to simulate sequentially; and being able to speed up the simulation compared to a sequential simulator. For proof of concept, we have implemented this technique for an execution-driven parallel simulator on the KSR-2, a cache-coherent shared memory machine, for a target architecture that uses an invalidation-based protocol. We validate the performance statistics gathered from this simulator (using traces) by comparing it against a sequential simulator. We show that the method is both viable and promises to offer significant speedups with the number of processors. We provide a detailed performance study of our technique using some benchmark application programs.

Key Words:

Parallel simulation, performance evaluation, cache consistency, execution-driven simulation, shared memory multiprocessors, performance debugging.

*This work has been funded in part by NSF PYI award MIPS-9058430 and a matching equipment grant from DEC.

1 Introduction

Shared memory multiprocessors usually have private caches associated with each processor. There are many parameters to be tuned with respect to the cache design such as the cache size, the line size, associativity, the replacement policy, and the protocol used for cache coherence. Thus cache simulations play a very important role in the design cycle of building shared memory multiprocessors by aiding the choice of appropriate parameter values for a specific cache protocol and estimating the performance of the system. Various simulation techniques including trace-driven [EK88, ASHH88], and execution-driven [Fuj83, CMM⁺88, DGH91] methods have been used for this purpose. Most of the known approaches to cache simulation are sequential. Such simulations impose a heavy burden on system resources both in terms of space and time. The elapsed time for the simulation is particularly limiting on the size of the system that can be simulated with realistic workloads. Given the availability of commercial multiprocessors it is attractive to consider their use in reducing the elapsed time for the simulation by parallelizing the simulation itself. The expected benefit is in being able to simulate larger parallel systems (both number of processors and problem size) than can be feasibly simulated sequentially (due to space and time constraints), and the potential for speeding up the simulation compared to a sequential simulator.

Parallel simulation techniques are viable if they result in speedups as more number of processors are employed in the simulation. Typically these techniques fall into two categories - *conservative* and *optimistic*. In conservative techniques two parallel units of work can be scheduled at the same time if and only if one is guaranteed not to affect the execution of the other [Fuj90, CM79]. From the point of view of simulating cache-coherent multiprocessors, such a restriction invariably inhibits the simulation from being able to exploit the available parallelism in the application. On the other hand, optimistic scheduling techniques such as Time Warp [Jef85] have not been used for simulating shared memory systems because a naive application of this technique could result in considerable state saving overhead that may dominate the execution.

We develop a new technique, called *timepatch*, that exploits the available parallelism in the application for driving the parallel simulation of caches for shared memory multiprocessors. The method is based on using application specific knowledge to yield a mechanism that is conservative with respect to generating a correct sequence of instruction execution (commensurate with the programming model), but is optimistic with respect to the timing information. Specifically, functional correctness of the simulated execution is ensured by executing the synchronization operations in the application faithfully as would be executed on the target parallel machine. The timing correctness of the simulation is accounted for at well-defined points in the application (such as synchronization points). Thus the technique widens the window over which units of simulation work can be executed in parallel without having to synchronize with one another for timing correctness com-

pared to conservative techniques. Further, since the technique never requires having to go back in simulated time (despite the optimism with respect to the timing information) there is no need for rollbacks (and the implied state savings) compared to optimistic techniques. Further we use application specific knowledge (that can be gleaned from the compiler) such as the data layout in the caches to reduce the overhead of simulation. The result is a significant speedup in simulation time for our technique which tracks the speedup inherent in the original parallel application.

The main contributions of this work are:

- a novel technique for parallel simulation of cache-coherent multiprocessors,
- development of performance enhancement strategies aimed at reducing the overheads of parallel simulation,
- a proof of concept prototype implementation that embodies the technique and the enhancements,
- performance results showing the improvement in performance with increasing number of processors.

In Section 2 we present the background and related work on which our research is developed. We next state our assumptions and develop the technique in Section 3. The implementation and related issues are outlined in Section 4. Section 5 gives validation and preliminary results of the implementation. We then identify the overheads in the simulator in Section 6, and suggest implementation ideas and optimizations to reduce these overheads. Using these optimizations, we show the improved performance of the technique for two applications in Section 7. Finally we present some concluding remarks and direction for future research in Section 8.

2 Related Work

Traditionally most cache studies have used either traces or synthetic workloads to drive the simulation. There are drawbacks to both of these approaches. Trace-driven simulation has some validity concerns as observed by several researchers [FH92, GH93, Bit89] due to the distortions that may be introduced due to the instrumentation code that is inserted for collecting the traces. These distortions include non-uniform slowdown of the parallel processes due to varying amount of tracing code in each process, and overall slowdown in the execution speed of all processes owing to tracing. Since the execution path of a parallel program depends on the ordering of the events in the program, both these distortions have the potential of completely changing the execution path unless timing dependencies are carefully eliminated from the traces [GH93]. Program startup effects may also distort the results, especially if the trace length is not long. Further, the traces obtained from

one machine may not represent true interactions in another machine. Lastly, the traces usually do not capture OS related activities (such as interrupts, context switches, and I/O) unless hardware instrumentation is available [SA88]. Many synthetic workload models have been proposed that could avoid the problems associated with traces [AB86, Pop90]. Since application characteristics vary widely, it is difficult to generate a synthetic workload model that is representative of the memory access pattern across a wide range of applications. The drawbacks with both trace-driven and probabilistic simulation can be overcome with an execution-driven simulator. In this approach, real applications are used as the workload on the simulated target architecture. Thus the observed memory access pattern will be the actual one that will be seen on the target architecture. The primary disadvantage of this approach is that it is extremely slow since each instruction has to be simulated for the new architecture in question.

A simple modification to the execution-driven simulation technique has the potential for considerably reducing the simulation time in an execution-driven simulator. In cache simulations, we are interested only in the processor interaction with the cache/memory subsystem. Thus, we simulate only those events that are external to the processor, i.e., those that interact with the memory subsystem and we let the other “compute” instructions execute on the native hardware. In our case, the events of interest include loads, stores and synchronization. This technique of trapping only on “interesting” events saves considerable simulation time and has been used by others [DGH91, BDCW91, CMM⁺88]. This method, often referred to as “program augmentation”, is certainly less expensive than execution-driven simulations in which every instruction is interpreted [Lig92]. An inherent assumption with this method is that instruction fetches do not affect the caching behavior of memory hierarchy. In spite of program augmentation, it may be infeasible (both in terms of space and time) to simulate large system and problem sizes with sequential simulation. Therefore, we explore methods of parallelizing the simulator in this research.

Synchronization of parallel simulators are often characterized as being *conservative* or *optimistic*. For example, in the conservative approach employed in the Wisconsin Wind Tunnel [RHL⁺92], only events that will not be causally affected by another event are processed in parallel. If t (called the *lookahead*), is the minimum time (for e.g. inter-processor communication time) required for one event to affect another event then we have a range of timestamps (from T to $T+t$, where T is the current lowest timestamp) that can be processed in parallel. Thus the parallelism is limited to the number of events that fall within this window of size t . Further, deadlocks are a potential problem with some conservative algorithms [CM79]. In the optimistic approach [Jef85], events are processed as soon as they are generated, as though they are independent of others. Such optimism might result in incorrectness in simulating the actual behavior of the application. This situation (when causal violations in processing events are detected) is rectified by rolling back the prematurely executed event computation to a previous correct state, and re-executing the computation to preserve the

causal dependencies. The optimistic approach requires preserving the necessary state information to restart computation in case of a possible rollback. This state saving could be a considerable overhead in simulating the cache behavior of shared memory parallel systems, though incremental state saving may alleviate this problem somewhat.

A parallel cache simulation scheme, based on a time-parallel simulation technique, using program traces has been proposed by Heidelberg and Stone [HS90]. A portion of the program trace is allocated to each processor. In this scheme, each processor assumes an initial state, and simulates its portion of the trace independent of the other processors. The statistics computed by each processor could be wrong due to an incorrect initial state. To address this situation, each processor gets its initial state from its logical predecessor and re-executes the simulation. This step may need to be repeated until the initial state of each processor matches the final state of its logical predecessor. The time-partitioning method is a fairly promising technique since typically there is just one repetition in a cache simulation because of the locality of references. However, it has the usual problem associated with trace-driven methods. In [HS90], it is also shown that it is sufficient to execute the traces for a set of cache lines instead of the entire cache. An implementation of a parallel trace-driven simulation on a MasPar is discussed in [NGLR92], which offers extensions to the above approach.

Dickens et al. [DHN94] suggest a technique for parallel simulation of message-passing programs. Their objective is to simulate the performance of these programs on a larger configuration of a target machine on a smaller host machine. The Wisconsin Wind Tunnel [RHL⁺92] uses a direct execution approach to simulate a shared memory multiprocessor on a message-passing machine. Using a portion of the memory at each node of CM-5 as a cache, WWT simulates a fine-grained version of shared virtual memory [LH89] through the ECC bits of the CM-5 memory system. The use of ECC bits allows WWT to avoid trapping on each memory operation compared to other execution-driven simulators. Thus only misses and access violations (which manifest as ECC errors in the WWT) are handled through special software trap handlers that simulate the target cache protocol. Using the minimum network latency Q as the *lag*, WWT implements a conservative parallel simulation technique requiring all processors to synchronize every Q cycles for processing the events generated in that window. Even though our goals are similar the approaches are orthogonal (see Section 3) and our technique can further benefit from ideas such as hardware assist to recognize events. Our approach for parallel cache simulation uses a technique that obviates the need for synchronization every Q cycles inherent in conservative approaches such as WWT.

3 The Timepatch Technique

The objective is to develop an execution-driven simulation platform that would enable gathering performance statistics (such as cache hit/miss rates, and message counts) of parallel programs executing on a *target* shared memory parallel machine. The target machine is simulated on a *host* which is also a shared memory parallel machine. Consider a shared memory parallel program with n threads to be executed on a n processor target machine, on which each thread is bound to a unique target processor. We use this program to drive our simulator on the host machine. We map each thread of the program to a separate physical processor of the host machine. Each host processor simulates the activity of the thread (mapped on to it) on the target processor. The simulation has to faithfully model the functional behavior of the original program as well as the timing behavior due to interprocessor communication and synchronization on the target machine. We assume a basic load/store type RISC architecture for the processors of the target machine where interprocessor interactions occur only due to memory reference instructions. We further assume that each target processor has a private cache which is maintained consistent using some cache consistency protocol. Thus the “interesting” events that have to be modeled for gathering the performance statistics of the memory hierarchy of the target machine are the load, store and synchronization operations. Only these interesting events trap into the simulator so that their behavior on the target machine can be modeled faithfully. Upon such traps, the simulator updates the state of the accessed cache block commensurate with the cache protocol implemented on the target machine and performs the intended operation (such as load/store of the data item). The “uninteresting” instructions in the thread are executed at the native speed of the host processor (i.e. they are not simulated at the instruction level). Instead, the time it takes to execute these instructions on the target machine is accounted for in the simulation.

As alluded to above, a simulation has to guarantee two kinds of correctness: *behavioral* and *timing*. A conservative simulation approach addresses both these correctness criteria simultaneously by never allowing event processing to get ahead of the permissible lag. Since no knowledge about the interaction between the events is available to the conservative simulator it must necessarily assume that any event can potentially affect another event outside the lag. In an execution-driven simulation of a shared memory parallel system it is possible to decouple the two correctness criteria as discussed below.

To ensure behavioral correctness it is sufficient if we “simulate” the synchronization events in the parallel program correctly (i.e. as they would happen on the target machine) since these events in turn guarantee the correctness of the shared memory accesses governed by them. The correctness of the shared memory accesses governed by the synchronization events is guaranteed because of the following reason. Our host machine is also a shared memory multiprocessor and thus will

reflect modifications to the shared state affected by the simulated parallel program. Simulating a synchronization event correctly implies ensuring that these events are executed in the same time order as in a conservative simulation, and providing a consistent view of the shared state of the parallel program to all the participating processors at such synchronization points. If the program uses implicit synchronization (i.e. it has data races), then behavioral correctness can still be ensured so long as such accesses can be recognized and flagged by the compiler.

The timing correctness criterion is achieved by a technique called *timepatch* which is described below. Each processor maintains its notion of simulated time which is advanced *locally*. The update of simulated time occurs due to one of two reasons. Firstly, upon executing a block of compute instructions on the host processor a call is made to the simulator to advance the time by the amount of time that block would have taken to execute on the target machine. Secondly, due to the traps into the simulator for the interesting instructions. The load/store events can be to either shared or private memory. These memory accesses may interfere with accesses from other processors of the target machine due to either true or false sharing on the target machine. However, each host processor simulates these load/store accesses as though they are non-interfering with other processors on the target machine and accounts only for the hit/miss timing. The potentially incorrect assumption that these accesses do not interfere with other processors may therefore result in the local notions of simulated time being inaccurate. Thus, at a synchronization point, these timing inconsistencies have to be fixed so that synchronization access is granted in our simulation to the processor that would actually be ahead in time on the target machine and therefore preserve behavioral correctness. Such timing inconsistencies can be corrected as follows. We maintain a history of all the memory accesses on a per processor basis. At synchronization points we merge these history logs to determine the ordering relationship between these accesses. Using this global ordering we can determine the inter-processor interactions (such as invalidation messages) that were previously not accounted and appropriately modify the notion of time of the corresponding processors. Details of how this reconciliation is done are presented in the next section.

The simulation technique outlined above is conservative with respect to the behavioral correctness since it faithfully executes the synchronization events in the parallel program in time order. However, it is optimistic with respect to timing correctness since it allows each processor to account for timing between synchronization points independent of other processors. The price for this optimism is the time overhead in performing the timepatch at synchronization points and the space overhead for recording the history of accesses made by each processor.

Figure 1 demonstrates the timepatch technique with an example. Let us say that the application uses 2 logical processors. We consider only load, store and synchronization operations since those are sufficient to illustrate our idea. Consider the events at time T_02 on processor 0 and T_12 on processor 1. As can be seen from Figure 1 there is no order implied between these two events. In

Figure 1: A Timepatch Example

our method, each logical processor is bound to a physical processor and execution is not stalled until synchronization points. Thus in our simulator these events can be processed in parallel. However, if we assume that $A1$ and $B1$ reside on the same cache line and that an invalidation-based protocol is in effect on the target processor, the events T_{02} and T_{12} could indeed affect each other. Assume that T_{02} (store to $A1$) occurs after T_{12} (load of $B1$) but before T_{13} (load of $B1$). In this case, this second load of $B1$ on processor 1 (event T_{13}) will be a miss due to the invalidation of that cache line by the store of $A1$ on processor 0 (event T_{02}). Observe that even though our hit/miss and timing information may be incorrect, the program's functional correctness is not violated because the shared memory is kept consistent by the underlying host processor. At synchronization points, the timepatch technique has to be applied and timing errors have to be fixed before granting these synchronization requests. Consider the events T_{03} and T_{15} that correspond to the lock requests on processors 0 and 1 respectively. Let us say that on the target processor, processor 0 gets the locks first. However in the simulation it is possible that processor 1 reaches the lock request before processor 0 does due to different speeds of the host processors. To ensure that the behavior on the target machine is accurately reproduced, timepatch is applied at T_{15} and it is determined that processor 0 is lagging behind processor 1 in simulated time and that processor 0 could possibly affect the outcome of this access. Based on this outcome, processor 1 is stalled until the simulated time of other processors (in this case only processor 0) advances to processor 1's current notion of time. Observe that while the timepatch operation is in progress only processor 1 is stalled waiting for other processors to cross time T_{15} so that it can be granted synchronization. The other processors can continue processing the events of their respective threads. Similarly if processor 0 arrived at the event T_{03} first it only needs to stall until processor 1 crosses T_{03} . A barrier is a

special synchronization operation and after this operation the simulated time on all the processors participating in the barrier is the same; i.e., values of T_{05} and T_{16} are exactly the same.

The above example illustrates how the timepatch technique works. In the next section, we detail the implementation of this technique on the KSR-2.

4 Implementation

4.1 Description

The target machine to be simulated is a CC-NUMA machine. Each node has a direct-mapped 64 KByte private cache. The shared memory implemented by the target machine is sequentially consistent using a Berkeley style invalidation based cache coherence protocol with a full mapped directory. We assume that local accesses (hits in the simulated cache) cost X cycles while remote accesses (misses in the local cache) cost Y cycles. We also assume that invalidations cost Z cycles irrespective of the amount of sharing. X , Y , and Z thus parameterize the latency attributes of the network that are relevant from the point of view of consistency maintenance.

The above assumption ignores the contention that could result on the network due to remote accesses generated from the processors. As a result the execution time for a parallel application may be worse than what we might observe. Further the performance statistics could also be affected by this assumption. The main motivation for not simulating the network activities in detail is the time overhead for simulating this aspect of the system architecture. The rationale for this assumption is as follows. In a well-balanced design of a parallel architecture one would expect that the network would be able to handle typical loads generated by applications. For example, experimental results on a state-of-the-art machine such as the KSR-2 have shown that the latencies for remote accesses do not vary significantly for a wide variety of network loads [RSRM93]. In [SSRV94], it was reported that the contention overheads observed in several applications were quite small. Recent studies [CKP⁺93] have also shown that parameterized models of the network may be adequate from the point of view of developing performance-conscious parallel programs. In any event, we do not expect the performance statistics gathered for the memory hierarchy to be affected significantly by ignoring contention since a high hit rate is expected in the private caches of a shared memory multiprocessor implying substantially small amount of network activity.

The host machine is KSR-2 [Res92]. KSR-2 is a COMA machine with a sequentially consistent memory model implemented using an invalidation-based cache coherence protocol. The interconnection network is a hierarchy of rings with 32 processors in the lowest level ring as shown in Figure 2. Each processor node has 512 KBytes of first level cache and 32 MBytes of second level cache. We use a 32-processor KSR-2 for our experiments. We map each node of the target machine on to a unique node on the host machine. The input to the simulator is a parallel program meant to be

Figure 2: Architecture of the KSR-2

executed on the target machine. As mentioned earlier in Section 2, we use program augmentation technique to execute the “uninteresting” non-memory reference (compute) instructions at the speed of the native host processor. The input program is augmented (currently by hand at the source level) with traps into the simulator for every load, store and synchronization operation.

Typically, cache simulations maintain the directory state of memory, the state of each of the caches and a notion of (global) simulated time. The timepatch approach uses the following information in addition to the above. We maintain a *local* notion of simulated time associated with each processor of the target machine. Events executed on a processor only modify this local time. The timing information is correct in the absence of interactions with other processors. To account for such interactions each processor maintains a table of timestamped events (of all its memory operations). The simulator also maintains a memory directory data structure. Each directory entry in this data structure contains the usual information needed for protocol processing. In addition, the memory directory also maintains a *last served* time which represents the completion timestamp of the last access serviced by the memory directory.

On a trap corresponding to a load/store event, the cache directory state is updated and (hit/miss) time is accounted for based only on the current cache state. Traditional cache simulations also check the state of the memory directory in order to determine if further coherence actions (such as invalidations) are required. We do not perform this step at this point of access. Instead, the processor creates an entry (see Figure 3) in its table which gives the current (local simulated) time, the memory address accessed, the type of operation and an indication if the operation was treated as a hit or a miss. Notice that this operation does not require interaction with any other processor and can proceed independently of other processors. Note also that the possible

Timestamp (Current Time)	Memory Address	Type of Access (Load or Store)	Hit or Miss? (Based on cache state)
-----------------------------	----------------	-----------------------------------	--

Figure 3: An Entry in the Timestamp Table

errors related to timing correctness are that we either treated a memory access as a cache access or that we did not account for the overhead of coherence maintenance. Consequently the local notion of time could be incorrect and possibly less than the “actual” value. For the compute instructions executed on the host processor, the local simulated time is updated based on the time it would have taken on the target processor.

As we mentioned in the previous section, to guarantee behavioral correctness it is necessary to ensure that the synchronization accesses in the parallel program be ordered faithfully in the simulation to correspond to their ordering on the target machine. Thus when a thread reaches a synchronization point in its execution it is necessary to reconcile all the per-processor local notions of simulated times to derive a correct ordering for the synchronization access. This reconciliation involves resolving inter-processor interferences that may have happened due to the load/store memory references that this thread generated up to the synchronization point.

The “timepatch” function (see Figure 4) is called by a processor to perform this reconciliation. A counter $addtime_j$ is associated with each processor j , in which the correction that needs to be applied to the local notion of simulated time is recorded by the timepatch function. Since all memory accesses have to go through the memory directory, it is the central point of conflict resolution for competing memory references from different processors. The timepatch function determines the timing correction that needs to be made to the accesses from each processor based on the interactions between accesses from different processors. This determination is done by applying these accesses to the memory directory when timepatch is called. First the accesses of the processors recorded in the respective timepatch tables have to be ordered before they can be applied to the memory directory. Since each processor timestamps its accesses in order, the local timestamp tables are already sorted in increasing time order. The timepatch routine has to merge all the local timepatch tables, apply them in order to the appropriate memory directory entries, determine the possible interactions among the accesses, and reconcile the ensuing timing inconsistencies. Before we start applying these accesses to the memory directory, we find the timestamp t_j of the last entry in each of the per-processor timestamp tables. We next determine the minimum value Min of the t_j ’s. Min represents a time up to which all processors have advanced in simulated time. Therefore all the accesses from the processors up to this point of time will be in the timepatch tables, and the potential interaction among these accesses can be resolved. We cannot handle events with timestamps greater than Min at this point because it is possible that the processor

associated with the current minimum Min (the one lagging behind in simulated time) may make accesses that could cause interactions with other accesses that happen in its “future”. The first unprocessed entry is picked from each of the local timestamp tables and inserted into a sorted tree if its timestamp is less than Min . Note that there is *at most* one entry per processor at a time in this tree. The record x_j with the minimum timestamp is deleted from the tree and the memory directory entry corresponding to this operation is updated. This update will also determine the increment (if any) that has to be applied to the counter $addtime_j$ of processor j . It should be clear that this increment can never be negative since we process the events in time order. There will be a non-zero increment when the interval between consecutive accesses to the same memory block is less than the servicing time for that access, and represents the queueing delay at the memory directory as well as the cost of consistency maintenance which were overlooked when the access was made. The timestamp of any entry accessed henceforth from the timestamp table corresponding to processor j is incremented by the value in $addtime_j$. If the increment has to be applied to the processor that determined Min originally, then Min will have to be recomputed. The next entry (if any remaining) from this processor’s timepatch table is inserted into the tree if it is less than the new Min . The above processing of entries from the tree continues until the tree is empty.

Upon return from the timepatch routine, all inter-processor interferences have been correctly accounted for up to time Min . If the processor that invoked this routine (upon reaching a synchronization point in its execution) still finds itself to be the least in simulated time then it can perform the synchronization access. If not, it would have to block until all the other processors have caught up with it in simulated time to make this determination. It should be noted that while a processor is performing timepatch, other processors can continue with their execution.

We will use the same example used in the previous section (Figure 1) to illustrate in detail how timepatch works. As before, we assume that $A1$ and $B1$ are located on the same cache line. The time order of the events shown in the Figure captures the order in which they should occur on the target machine. Again, we assume that host processor 1 executes faster than host processor 0, and gets to T_{15} . Suppose that the only entry in the table associated with processor 0 at this point is T_{01} . In the timepatch routine if we process T_{13} then we would not be able to consider the effect of T_{02} on T_{13} since T_{02} has not yet occurred. Thus in this case timepatch should only consider events up to time T_{01} . In the meanwhile, processor 1 has to stall until processor 0’s time is at least T_{15} . Eventually processor reaches T_{03} and timepatch is invoked again because of the synchronization operation. Now both processors 0 and 1 are waiting for the synchronization access. The timepatch routine determines that T_{03} is lesser than T_{15} and grants synchronization access to processor 0. Observe that this is the desired behavior on the target machine.

There are certain subtle cases arising due to the semantics of synchronization events which the implementation has to take care of. Barrier is one such. In this case, the table entries of all the

```

Begin Mutex /* only one processor can perform this action at a given instant */
  (1) for each processor  $j$  initialize a counter  $addtime_j$  to zero
      /* this keeps track of the correction that needs to be applied
      * to the local notion of that processor's time
      */
  (2) determine  $t_j$ , the timestamp of the last entry in each of the
      per-processor tables, and find the minimum  $Min$  among these.
      /* timepatch can be performed only up to this time  $Min$  */
  (3) pick the first unprocessed event  $x_j$  from each per-processor table
  (4) for each  $x_j$  if (  $x_j.timestamp < Min$  )
      (4:1) insert  $x_j$  into tree sorted by the timestamp  $x_j.timestamp$ 
      end for /* end of (4) */
  (5) while (tree not empty)
      (5:1) delete a node  $lt$  with lowest timestamp from the tree
          (say it belongs to processor  $j$  - then  $lt = x_j$  )
      (5:2) apply the access of  $lt$  to the corresponding memory directory
          and set  $flag$  if timing inconsistency detected
          /* this will update the state of the memory directory entry
          * and the timestamp associated with this memory directory
          */
      (5:3) if (  $flag$  is set ) /* implies timing inconsistency */
          (5:3:1) increment the counter  $addtime_j$  appropriately
          (5:3:2) Recompute  $Min$ 
          end if /* end of (5:3) */
      (5:4) pick the next unprocessed entry  $x_j$  for processor  $j$ 
      (5:5) increment  $x_j.timestamp$  by  $addtime_j$ 
      (5:6) if (  $x_j.timestamp < Min$  )
          (5:6:1) insert  $x_j$  into the tree
          end if /* end of (5:6) */
          /* continue processing until tree is empty */
      end while /* end of (5) */
End Mutex

```

Figure 4: Pseudo-code invoked to patch time

processors participating in the barrier have to be cleared when the last processor arrives at the barrier irrespective of *Min*. The synchronization traps into the simulator handles such cases correctly.

4.2 Practical Considerations

While timepatching is strictly required only at synchronization points for the correctness of the proposed technique, we are forced to do it more often due to space constraints since it is infeasible to maintain very large tables for the timepatch entries. The main idea behind timepatch is to increase the window of time over which it is possible to have parallel execution of the simulated threads of the target architecture. This window gets shrunk a little due to performing timepatch more frequently, but it has the beneficial side effect of advancing the global simulated time, deleting some of the entries from the local timestamp tables, and thus clearing up resources that can be reused.

5 Preliminary Results

There are two aspects to be evaluated to appreciate the merit of our technique. The first is validation of the technique itself to ensure that the performance statistics of the target architecture obtained using our technique is correct. The second is the speedup that is obtained from the parallel simulator. Ideally, we would want to see the speedup curve of the parallel simulator to track the speedup achievable in the original application. However, this depends on how the overheads in the simulation itself get apportioned among the participating processors. We first address the validation question.

5.1 Validation

We developed a sequential simulator that models the same target machine using CSIM [Sch90], which runs on a SPARC workstation. In order to validate our parallel simulator we used randomly generated traces to drive the sequential and parallel simulators. The performance statistics used to verify the parallel simulator are the simulated cycles (for performing all the memory references in the traces) and the message counts (number of messages generated due to write invalidation). The validation results are shown in Table 1. The traces consist of only load and store references and different proportions of read to write ratios. One of the traces shown has 5000 references and the other has 10000 references. The message counts for the two cases are off by at most 2% for the traces considered. The agreement in simulated times is within 2% for one trace and varies between 7% and 12% for the other trace. CSIM is a process oriented simulation package, which schedules the CSIM-processes in a non-preemptive fashion within a single Unix process. We do not have

Application	Processors	Simulated Cycles			Message Counts		
		Sequential	Parallel	Difference	Sequential	Parallel	Difference
Trace-5K	4	671490	670395	0.16%	6045	6040	0.08%
Trace-5K	8	790010	788600	0.18%	13055	13039	0.12%
Trace-5K	16	868520	883835	-1.76%	27095	27087	0.02%
Trace-10K	4	1519895	1703035	-12.04%	11151	11377	-2.02%
Trace-10K	8	1660345	1781825	-7.32%	27765	27881	-0.41%
Trace-10K	16	1757455	1895990	-7.88%	59980	60010	-0.05%

Table 1: Validation of the Parallel Simulator

any control over the internal scheduling policy that CSIM uses for scheduling the runnable CSIM-processes. We believe that the differences observed for the second trace are due to the effects of this scheduling policy. Overall the validation results indicate that our parallel simulator simulates the target machine with reasonable accuracy.

5.2 Speedup Result

Next we address the speedup question. In order to illustrate and understand the performance of our simulation technique, we will concentrate on the matrix multiplication application. The matrix multiplication problem can be easily parallelized without any false sharing (except for boundary conditions). True sharing is only for read-shared data and thus there is no synchronization in the code. As expected, the raw code we developed for the matrix multiplication application shows linear speedup on KSR-2. Thus we expect that the parallel simulator which uses the same code with augmentation will track the speedup of the application program and give similar speedups. Consider the performance of our simulator when we use 64x64 matrix multiplication to drive our simulation. These results are shown in Table 2. As seen from the Table the speedups observed are not close to what we expect. This is because of the overheads in the simulation. In the next section we analyze what these overheads are and what implementation techniques can be used to reduce these overheads and thus speedup our parallel simulator.

6 The Anatomy of the Parallel Simulator

While performing an execution-driven simulation there are two costs involved - that of the actual application and the simulation overhead (see Figure 5). Let us consider how these costs vary as we simulate different numbers of target processors. For a given problem size, the amount of

Processors	Simulation Time*	Speedup
1	44.27	n-a
2	34.96	1.26
4	31.80	1.39
8	31.23	1.41
16	185.55	0.23

* Wall clock time in seconds.

Table 2: Simulation Times for 64x64 Matrix Multiplication

Application Time	Simulation Overhead (Event Processing + Scheduling Costs)	Sequential
Application Time	Simulation Overhead (Event Traps + Timepatch)	Parallel

Figure 5: Expected gains using parallel simulation

processor cycles used by the application (assuming a deterministic computation) in a sequential setting is almost a constant since the problem that has to be executed has not changed, irrespective of the number of processors simulated. However, simulating more processors adds to the simulation overhead in the sequential setting because of additional process management and other effects such as decreased cache locality. Now let us consider our parallel simulator. The application time is unaffected by our simulation methodology and hence the available parallelism in the application should be observed in our simulation method as well. The real question is how the simulation overhead is apportioned among the processors when we simulate larger numbers of target processors. The simulation overhead can be broken down into two components: (i) timestamping and local state maintenance on each memory access, and (ii) timepatching at synchronization points. The first component includes the traps incurred for loads and stores. Since these traps and ensuing state maintenance activities are local to each processor, they are done in parallel without interfering with other processors. Therefore assuming that the total number of loads and stores remains a constant for a given problem size the overhead due to the first component also should exhibit the same speedup properties as the application itself, and thus should not limit the speedup of the simulation. The second component of the simulation overhead includes fixing timing errors as well as waits incurred due to local timepatch tables filling up. It is the timepatch function that can be performed only by one processor at a given instant and is the source of the sequential bottleneck in the simulation.

Figure 6: Comparative costs in the 64x64 Matrix Multiplication

To investigate the cause for the relatively poor performance of the simulation we profiled our simulator in order to understand where the time is spent. Figure 6 shows the per-processor breakdown of the various costs involved for different numbers of processors. The application time is itself negligible (less than 1 second for 16 processors). The breakdown gives the time to perform the load traps (labeled *Load* in Figure 6), the store traps (labeled *Store*), the time to perform the timepatch operation (labeled *Patch*), the wait time experienced because the timestamp table is full (*Wait for patch at table full*), and the wait time for the timepatch operation to complete at synchronization (*Wait for patch at synchronization*). The load and store traps are application dependent and are inevitable. The costs associated with performing timepatch and the waits are the simulation overheads of our technique and our aim is to make them as small as possible. From Figure 6, we see that the costs for load/store traps decrease proportionally as we increase the number of processors since this work gets divided among the processors. In the 4 processor case we observe that the wait times due to the timestamp tables becoming full is a significant portion. This preliminary implementation uses a table size of 5K entries per processor. Thus the tables get filled up quite quickly. This forces a processor to attempt to perform a timepatch operation. But if some other processor is already in timepatch then this processor has to wait until some space is freed up in its local table. So reducing the wait time at timepatch is an important step for speeding up the simulation. Another observation from the chart is that the cost to perform the timepatch operation is a significant portion of the total time. Thus another avenue for speeding up the simulation is to speed up the execution of the timepatch operation. The wait time for patch at synchronization is a

Figure 7: Matrix Multiplication revisited with frequent patching and large table size

subtle issue. If the application has little serial overhead and no work-imbalance, then there should not be any significant waiting at synchronization. The waiting that we do see in Figure 6 is brought about by a processor having to wait at a barrier for some other processor to finish timepatching. In fact, this waiting will go away if we reduce the patch overhead.

In the following subsections, we explore methods to cut down these overheads.

6.1 Reducing the Wait Time at Patch

The processor that is ahead in simulated time will eventually be blocked at a synchronization access. Therefore, one possibility to reduce the wait times at timepatch is to make this processor perform the timepatch operation. Clearly, the total execution time for the simulation cannot be less than the cumulative patch time since timepatch is essentially a sequential process. However, it can be seen from Figure 6 that the total sum of the patch times observed on all the processors is close to the execution time. Therefore, throttling the fastest processor is not going to help. On the other hand, if the size of the timepatch tables are increased then that would reduce the number of trips to timepatch that each processor would have to make and therefore reduce the amount of waiting that each processor would have to do at timepatch. Figure 7 shows the effect of table size on the execution time. As can be seen with a table size of 500K entries, the waiting time at patch is almost close to zero. Also, comparing Figures 6 and 7 it can be seen that increasing the frequency of the timepatch operation did not increase the overall work to be done by the timepatch function.

6.2 Distributing the Patch Work

In our current implementation, the biggest source of simulation overhead is the patching itself. In the current setup this is done sequentially. One possibility to reduce the patch overhead is to parallelize it. A simpler and quicker option is to do the timepatch more often so that it can be overlapped with useful computation on other processors. One way of accomplishing this goal is by performing timepatch periodically instead of waiting until a synchronization operation or until the table is full. In the current implementation timepatch is called every 4096 load/store references. This frequent timepatching in conjunction with the increased table size improves the chance of patch overhead getting distributed among the processors and reduces the possibility of processors waiting at patch when someone else is doing it (see Figure 7).

6.3 Reducing the Patch Time

Given that timepatch is the dominant source of overhead we turn our attention to seeing if that work itself can be reduced. It is instructive to see the number of timepatch entries that are created and the actual number of them that impact the simulated time. For example, in matrix multiply with 16 processors, 798,916 timepatch entries are created but only 61,742 entries (less than 7%) actually result in change to the simulated time due to the inter-processor interferences. It turns out that it is possible for the compiler to predict which references will result in interferences from the data layout the compiler employs for the shared data structures in the caches. Therefore, if this knowledge is available to the simulator then it can eliminate a sizable number of the entries from the timepatch table. We did this optimization for the applications that are considered here. There are three kinds of data: private, true-shared, and false-shared. It is possible for the compiler to distinguish these categories of data, and this information can be made available to the simulator. The simulator should create patch entries for all false-shared data since they could cause interference depending on program dynamics. The simulator does not have to create patch entries for private data since the data layout of the compiler ensures no interference with other processors. The true shared data gets shared across synchronization regions in the program. Thus within a synchronization region it is sufficient if there is at least one patch entry for the first access for each such variable in that region by a processor.

We modified our implementation to use these optimizations. Associated with each cache block is a timestamp that gives the last access to that cache block. We associate a *sync-time* with each processor. This is the timestamp of the last synchronization operation carried out by this processor. The augmentor which generates the load/store traps gives this additional information whether the access is to private, false-shared, or true-share data. Upon every true shared access the timestamp in the referenced cache block is checked against the sync-time for that processor. If the sync-time

Processors	Unoptimized time (Secs)	Optimized time (Secs)	Improvement over Unoptimized	Speedup (for optimized)
1	68.20	39.28	42%	1
2	35.22	17.82	49%	2.2
4	26.65	13.85	48%	2.8
8	29.19	10.61	63%	3.7
16	160.15	56.16	65%	0.6

Table 3: Comparing the optimized and unoptimized Matrix Multiplication Simulation

Processors	Unoptimized time (Secs)	Optimized time (Secs)	Improvement over Unoptimized	Speedup (for optimized)
1	164.20	94.01	42%	n.a
2	131.18	45.53	65%	2.1
4	131.35	33.41	74%	2.8
8	241.61	52.55	78%	1.7
16	1301.11	398.21	69%	0.2

Table 4: Comparing the optimized and unoptimized Integer Sort Simulation

is greater then an entry is created for this reference in the patch table. An entry is created for every false-shared access and none for private.

With these optimizations the number of timepatch entries that are actually processed during the entire simulation is down from 798,916 for 16-processor matrix multiply to 267,636 (by a factor of 3). This is still around a factor 4 more than the number of entries that actually cause timing errors. By a more careful analysis and labeling of the accesses we expect to bring down this number even further.

The cache statistics (such as message counts and hit rate) observed for the optimized and unoptimized versions were the same indicating that these optimizations are indeed correct. Since the objective here is to show the viability of our simulation technique these performance statistics are not germane to the rest of the discussion. In the next section we present the speedup results from the optimized simulator for two application programs: matrix multiply, and integer sort.

7 Results from the Optimized Simulator

Tables 3, and 4 show the execution times and speedups for matrix multiply and integer sort.

Application	Processor id	User Time			Wall Clock Time		
		Load+Store	Wait	Patch	Load+Store	Wait	Patch
16-processor Matrix Multiplication	Processor 0	1.51	0.47	7.653	1.82	15.26	37.39
	Processors 1-15	1.49	1.55	0.002	1.96	53.30	0.05
8-processor Integer Sort	Processor 0	10.31	1.55	4.06	18.21	14.86	48.88
	Processors 1-8	9.41	1.78	2.54	11.57	24.82	3.43

Table 5: Breakdown of the user and wall clock times

As can be seen, we do get a reasonable speedup up to 8 processors for matrix multiply (3.7 for 8 processors), and up to 4 processors for integer sort (2.8 for 4 processors). Comparing the execution times of the optimized and unoptimized versions of the simulator we can see that the optimizations give a significant payoff (ranging from 42% to 78%). Since both versions use the same table sizes and periodicity for timepatch, the reduction in time is entirely due to the compile time optimizations which we discussed in Section 6.3.

Now let us try to understand the reason for slowdown beyond 8 processors for matrix multiply and 4 processors for integer sort. Table 5 shows the breakdown of the execution times for 16 processor matrix multiply, and 8 processor integer sort. The column labeled *user time* is the time spent in the simulator; the *wall clock time* is the elapsed time seen for the simulator. As can be seen one processor (labeled 0 in the Table) does most of the patching in matrix multiplication. The cumulative user time spent in patching was observed to be commensurate with that for lesser numbers of processors. However, it is seen that the wall clock time is greater than this patch time by 29.74 Secs. This is additional time spent by processors 1-15 waiting at the synchronization point for the patch function on processor 0 to complete. We believe we know exactly why this behavior is observed. KSR-2 has 32 MBytes of second level cache, and it allocates space for an entire page (of 16 KBytes) on every second level cache miss. Each per-processor patch table is a 2 Mbyte data structure. We believe that with 16 processors, the necessity to consult the tables of other processors at patch time results in a considerable amount thrashing of the second level cache leading to poor overall performance. This is the same effect which is observed in integer sort beyond 8 processors. Needless to say, that this behavior is purely an implementation quirk and does not impact the usefulness of the timepatch technique. In fact, we expect to be able to fix this interaction between the simulation data structures and the paging behavior of the operating systems by careful data partitioning.

8 Concluding Remarks

We developed a new method for parallel simulation of multiprocessor caches and have shown its feasibility by implementing it on the KSR-2. The primary advantages of this scheme are that we can obtain reasonable speedups limited primarily by the application speedups and that this method can be used to simulate larger parallel systems (both number of target processors and problem size) than is possible with a sequential simulator.

In the process of implementing the technique on KSR-2 we learned several lessons which are of interest from the point of view of performance tuning parallel applications in general, parallel simulators in particular. The first has to do with the potential for considerable speedup for parallel simulation of multiprocessor caches by gleaning compile time information on the data layout in the caches and passing it on to the simulator. The second is the importance of distributing the overhead of the simulation among the processors so that useful work in other processors can be overlapped with this overhead function. The last is the necessity to worry about the operating system interactions in a parallel machine such as the KSR-2. In particular, one has to carefully orchestrate the interactions between the shared data structures in the application and the paging policies of the operating system. In fact, this last point is not resolved fully in our current implementation. But we are sure that we can get it resolved and show considerable speedups for larger numbers of processors.

There is at least one architectural implication suggested by this parallel simulation exercise. It is clear that the performance of our technique can benefit from a “snoopy-read” primitive. The semantics of this primitive is to read the current value of a variable without changing the (exclusive) state of the cache line on the processor from which the value is being read. The timepatch routine could make heavy use of this feature. In the absence of such a primitive, the referenced cache line thrashes between the processors and not only slows down the execution on the affected processors but also places considerable stress on the interconnection network.

There are several directions to extend our work. One direction is to figure out a way to incorporate network contention of the target architecture into the simulator. This direction would allow extending our technique to simulate both memory and I/O intensive applications (which may stress the network) in addition to the compute intensive ones we have studied so far. A possible approach to incorporate the network would be to combine our method with an optimistic scheme such as Time warp to simulate the network messages.

A second direction is to use this technique to compare different memory systems employing different models of consistency and cache coherence strategies. A third direction is to simulate larger configuration of target architectures on smaller host machines. In our implementation, we used one host processor to simulate one target processor. The timepatch technique does not place

any such constraints and we could just as easily have mapped multiple nodes of the target machine to a single processor of the host machine. We also assumed that each target processor has only one thread of the application mapped to it. To relax this restriction we have to take into account the scheduling strategy on the target machine so that the cache effect produced by multiple threads on a processor can be accurately modeled.
