C. L. Liotta, Chairman

J. W. Bertrand
R. H. Felton

Date approved by Chairman: 3/12/73

## ACKNOWLEDGMENTS

The author would like to thank Dr. C. L. Liotta for suggesting the problem and especially Dr. J. A. Bertrand whose guidance and patience made this study possible. The author gratefully acknowledges the assistance of the members of the research groups of Dr. Bertrand and Dr. Liotta. The author also wishes to thank Dr. R. H. Felton for reading the final manuscript.

The author wishes to express appreciation to her husband Heinz for his love and understanding during the course of her graduate studies.

The author would also like to thank the Georgia Institute of Technology for financial assistance.

## SUMMARY

The molecular structure of crystalline bicyclo [2.2.2] octyl-2 p-bromobenzenesulfonate has been studied by examination of $x$-ray diffraction data collected using zirconium filtered molybdenum $K \alpha$ radiation with the object of discovering if the bicycloöctane group was twisted about the bridgehead-bridgehead axis. The molecule crystallized in space group $\mathrm{P}^{2} 1$ with four molecules per unit cell. The best model attained indicated some twist, although problems in the data set did not allow sufficiently accurate refinement for the angle of twist to be determined conclusively.

## CHAPTER I

## INTRODUCTION

In the past decade there has been considerable interest in the conformation of bicyclo [2.2.2] octane and its derivatives. Studies of the parent compound itself and of bicyclo [2.2.2] octane systems substituted at one or both bridgehead carbons have been undertaken but nothing has been reported concerning the conformation of bridge substituted bicyclo [2.2.2] octane systems. One reason for interest in such systems is their usefulness in the study of electrostatic effects in organic molecules. A system whose geometry is accurately known is advantageous in the study of the transmission of the effect of a dipole upon a reaction center through space because the distance, $\vec{R}$, from the center of a dipole to the reaction center and the angle ( $\theta$ ) which $\vec{R}$ makes with the direction of the bond moment must be known in order to calculate the $\log$ of the ratio of the dissociation constant of the substituted compound to that of the parent hydrocarbon $\left[\log \left(\mathrm{K}_{\mathrm{x}} / \mathrm{K}_{\mathrm{H}}\right)\right]$ according to the expression:

$$
\log \frac{K_{x}}{K_{H}}=\frac{e \mu \cos \theta}{2.3 k T R^{2} D_{E}}
$$

where $e$ is the electronic charge, $\mu$ the difference in group or bond moment between the substituent and hydrogen, $D_{E}$ is the effective dielectric and KT has its usual meaning. The studies which have been carried out on bicyclo [2.2.2] octane and related bridgehead substituted compounds have differed in their conclusions. Some favored a rigid molecule with the cis hydrogens on each bridge eclipsed. Some favored a molecule twisted about the bridgehead - bridgehead axis. Still others concluded that there are two energy minimums corresponding to the twisted conformations separated by an energy hump which is much lower than the energy available at room temperature. The results are inconclusive and still a matter for argument.

One of the earliest conformational studies of a bicyclo [2.2.2] octane compound was the analysis of the microwave spectrum of 1-bromo and 1-chlorobicyclo [2.2.2] octane by Nethercot and Javan ${ }^{1}$. They concluded that if there were an angle of twist about the symmetry axis, it was small, $0^{\circ} \pm 4^{\circ}$. Somewhat later Turner, Meador, and Winkler ${ }^{2}$ determined the heats of hydrogenation of bicyclo [2.2.2] octadiene and bicyclo [2.2.2] octene. They considered the heat of hydrogenation of bicycloöctene to bicycloöctane ( $-28.3 \mathrm{kcal} / \mathrm{mole}$ ) to be suprisingly high in view of the two 1:2- and two 1:3- eclipsed hydrogen interactions which are introduced. One explanation which they
suggested was that a twist about the central axis accompanied the hydrogenation process, and thus somewhat relieved the interactions and accounted for a larger total energy change. They favored, however, an alternative explanation in light of the heat of hydrogenation of bicycloöctadiene to bicycloöctene ( $28.0 \mathrm{kcal} / \mathrm{mole}$ ) which they considered also abnormally high. They suggested that if twisting of bicycloöctene were also permitted there would be an increase in torsional strain of the double bond which would cause an increase in the heat of hydrogenation of this substance. There would also be an increase in the heat of hydrogenation of bicycloöctadiene to bicycloöctene because the twisting in the product would relieve the two 1:2- and two 1:3- hydrogen-hydrogen interactions introduced. In either case they favored some degree of twisting about the central axis of bicycloöctane. They maintained that twisting to about $10^{\circ}$ could be accommodated without distortion of bond angles.

Macfarlane and Ross ${ }^{3}$ then analyzed the vibrational spectrum of bicyclo [2.2.2] octane. They predicted eight fundamentals active in both the infrared and the Raman region for bicycloöctane with $D_{3 h}$ symmetry (cis hydrogens eclipsed), and sixteen active in both regions for bicycloöctane with $D_{3}$ symmetry (twisted). They found only eight coincidences between Raman and vapour or solution infrared frequencies. They concluded that the agreement of the
number of coincidences and the comparative simplicity of the spectrum were compatable with the $D_{3 h}$ conformation. However, they recognized that if the skeletal twisting were slight the breakdown of selection rules would be inconsiderable and the spectral consequences would be difficult to recognize. They, therefore, concluded that if there is twisting it must be slight.

The first attempt to evaluate angle strain effects by implicit calculation and thus determine the conformation of bicyclo [2.2.2] octane was made by Gleicher and Schleyer ${ }^{4}$. Using the Westheimer approach the total strain energy was considered to be the sum of various independent strain-producing mechanisms, as expressed in terms of energy according to the following equation:

$$
\begin{gathered}
E_{\text {total }} \text { strain }=E_{\text {bond }} \text { length strain } \\
+E_{\text {bond }} \text { angle strain }+E_{\text {torsional }} \text { strain } \\
+E_{\text {nonbonded interaction }} \text { strain }
\end{gathered}
$$

An initial geometry was assumed for the molecule, the strain energy was calculated for this geometry, and then the coordinates of each atom were varied until an energy minimum was reached. Contrary to the conclusions which Turner, Meador, and Winkler ${ }^{2}$ drew from their heats of hydorgenation data,

Gleicher and Schleyer's calculations favored the conformation having $D_{3 h}$ symmetry. They also stated that rather than helping the torsional strain as Turner, Meador, and Winkler proposed, twisting about the central axis might increase the strain. Gleicher and Schleyer also considered the bridge-head-bridgehead nonbonded repulsion to be of importance. They concluded that if the molecule were twisted the internuclear distance between bridgeheads would be shorter, thus increasing the already appreciable nonbonded repulsions.

One of the first important $x$-ray analyses carried out on a bicyclo [2.2.2] octane system was done by Ermer and Dunitz ${ }^{5}$ on bicyclo [2.2.2] octane-1, 4-dicarboxylic acid. They found that the crystals were monoclinic, in space group $\mathrm{P} 2_{1} / \mathrm{C}$ and had four molecules per unit cell. They observed about 1150 reflections and refined to $R=0.066$. Their final structure indicated no significant deviation from $D_{3 h}$ symmetry in the carbon skeleton, and they found good agreement with the chemically equivalent bond distances from the calculations of Gleicher and Schleyer ${ }^{4}$. The conclusion that the $D_{3 h}$ symmetry arises neigher from rapid interconversion of the two $D_{3}$ enantiomers nor from disorder caused by random occupation of the molecular sites by $D_{3}$ enantiomers was supported by nearly spherical electron-density maxima corresponding to the methylene carbon atoms. Also, the absolute entropy calculations of Amzel, Cucarella and Becka ${ }^{6}$ indicate that there is no residual entropy, "thus excluding the possibility
of a diffraction $D_{3 h}$ symmetry being due to the coexistence of the two twisted $D_{3}$ forms at low temperatures ${ }^{6}$." However, the results of the $x$-ray analysis of 1 -p-bromobenzenesulphonyloxymethylbicyclo [2.2.2] octane (I) carried out by

Cameron, Ferguson, and Morris ${ }^{7}$ indicated $D_{3}$ rather than $D_{3 h}$ symmetry. The group of atoms $C(2) C(6) C(7)$ was rotated $3^{\circ}$ about the $C(1)$. . . $C(4)$ axis with respect to the $C(3) C(5)$ C(8) group. This twist results in the following torsional angles: $4.7^{\circ}$ at $C(2)-C(3), 5.1^{\circ}$ at $C(5)-C(6)$, and $5.4^{\circ}$ at $C(7)-C(8)$, all significantly non-zero. The fact that the 1,4 non-bonded distances, $C(2)$. . . $C(5), C(3)$. . $C(7)$, and $C(6)$. . . $C(8)$, are all approximately equal and significantly shorter than the analogous l,4 non-bonded distances, $C(2) . . . C(8), C(3) . . . C(6)$, and $C(5) . .$. $C(7)$, also supports $D_{3}$ symmetry. The crystals were monoclinic, in space group $\mathrm{P} 2{ }_{1} / \mathrm{C}$, and had four molecules per unit cell. There were 1715 data and the refinement was carried out to $R=0.104$. The observation was made that the structure was determined for a solid and the probable low energy barrier to bridge flipping in the bicycloöctane part of the molecule would lead to a conformational mixture in solution. Ermer and Dunitz ${ }^{8}$ then calculated a potential energy surface for
bicyclo [2.2.2] octane using semi-empirical potential functions, assuming $D_{3}$ symmetry. Their calculations indicated that the energy minimum might be slightly displaced from $D_{3 h}$ symmetry, but with a barrier between the two minima of only approximately $0.1 \mathrm{kcal} / \mathrm{mole}$. They then concluded effective $D_{3 h}$ symmetry at all temperatures as far as diffraction methods were concerned.

Wong and Westrum ${ }^{9}$ calculated the enthalpies of (hypothetical) hydrogenation of bicyclo [2.2.2] octane to ethylcyclohexane and of ethylcyclohexane to n-octane from the standard enthalpies of formation of the compounds. From these values they calculated the strain energy of bicyclo [2.2.2] octane (liquid) to be approximately $9.2 \mathrm{kcal} / \mathrm{mole}$. They suggested that this strain energy can be explained by three pairs of eclipsed hydrogens as approximated from the internal rotation energy barrier of ethane to be $8.7 \mathrm{kcal} / \mathrm{mole}{ }^{9}$. This would be the case in a molecule of the compound possessing $D_{3 h}$ symmetry.

A gas electron diffraction study of bicyclo [2.2.2] octane was carried out by Yokozeki, Kuchitsu, and Morino ${ }^{10}$. Their results supported the semiempirical calculation of Ermer and Dunitz ${ }^{8}$. They found that the shape of the potential energy function derived from their analysis was significantly dependant on assumptions about the force constant for the torsional motion about the $C(2)-C(3), C(5)-C(6)$, and
$C(7)-C(8)$ bonds of II. The most realistic of the potential functions used gave a potential hump of $75 \pm 100 \mathrm{cal} / \mathrm{mole}$ at the $D_{3 h}$ position and a broad double minimum at about $\phi=11^{\circ}$, where $\phi$ is the dihedral angle between the $C(1)-C(2)-C(3)$ and $C(2)-C(3)-C(4)$ planes. The analysis showed a classical turning point (the angle at which the potential energy is compariable with thermal energy at room temperature) of $21.5^{\circ} \pm 0.5^{\circ}$ and a rms angle of $12.0^{\circ} \pm 1.5^{\circ}$ in terms of $\phi$, and a classical turning point of $12.8^{\circ} \pm 0.3^{\circ}$ and a rms angle of $7.2^{\circ} \pm 0.9^{\circ}$ in terms of the angle of twist $\tau$ (the dihedral angle between the $C(1)-C(2)-C(4)$ and $C(1)-C(3)-C(4)$ planes). In general the study concluded that the molecule has a "floppy structure in thermal equilibrium as regards the twisting motion, ${ }^{10 "}$ and because the potential hump at the $D_{3 h}$ position is probably much lower than the thermal energy at room temperature the "molecule may be said to have a 'quasi-D 3 h structure' ${ }^{10}$."

This view of bicyclo [2.2.2] octane is supported by the microwave spectrum of 1-fluorobicyclo [2.2.2] octane and the review of the microwave spectrum of l-chlorobicyclo [2.2.2] octane analyzed by Horotall. The analysis of the spectrum of the fluoro compound indicated that there were two nearly equally intense strong lines and there was a progression, which was regular on the high-frequency side of the strong lines, and which became irregular near the ground-state line. These features indicated to Hirota that the spectrum was
indicative of a double-minimum potential. The final value of the potential hump between the two minima, $\mathrm{V}_{\mathrm{O}}$, was determined to be $191 \pm 52 \mathrm{cal} / \mathrm{mole}$ and the equilibrium torsional angle, $\phi_{0}$, to be $16.4^{\circ} \pm 2.6^{\circ}$. The spectrum of the chloro compound was reanalyzed and a double minimum potential for the torsional motion was also indicated. The calculated values for $V_{0}$ and $\phi_{0}$ based on the spectrum of the chloro compound were respectively $134 \pm 67 \mathrm{cal} / \mathrm{mole}$ and $16.2^{\circ} \pm 4^{\circ}$. The values for the two compounds agreed within experimental error although the chloro potential barrier seemed to be somewhat lower.

In conclusion, studies have been carried out which provide evidence for each of the three possible conformations of bycyclo [2.2.2] octane to the exclusion of the others, although the evidence does seem to favor either $D_{3 h}$ symmetry or a double minimum with the twisted conformers in thermal equilibrium. Also, there has been little definitive work done at all on bridge-substituted derivatives of bicyclo [2.2.2] octane. To date the matter remains unsettled and it was the purpose of this study to shed more light on the subject.

## CHAPTER II

## INSTRUMENTATION

Melting points were taken with an instrument from MelTemp. A Roto-Vac-Flash Evaporator from Buchler Instruments was used for solvent evaporation.

Initial crystal alignment and orientation were achieved using a Mark II Precession Camera and a Picker X-Ray Generator with a Dunlee molybdenum fine focus x-ray tube. The intensity data was collected with a Picker Four Circle Automated Diffractometer coupled with a modified IBM 026 Keypunch. Zirconium filtered molybdenum $\mathrm{K} \alpha$ radiation ( $\lambda=0.7107$ ) was used in the collection of intensity data. For the final data set, a crystal was placed in a glass capillary which was sealed and mounted on a STOE Eucentric Goniometer Head, 63.97 mm , with locks. The Burroughs 5500 and the Univac 1108 computers were used for computations.

## CHAPTER III

## EXPERIMENTAL

## Preparation of Compound and Analysis

Preparation of Bicyclo [2.2.2] octyl-2 p-bromobenzenesulfonate Bicyclo [2.2.2] octanol-2 was synthesized by the method of Brown and Geoghegan ${ }^{12}$. In a 125 ml erlenmeyer flask, fitted with a magnetic stirrer, was placed 2.94 g (9.24 mmoles) of mercuric acetate. To this flask was added 9.24 ml of water, followed by 9.24 ml of tetrahydrofuran. At this point a yellow suspension formed; 0.976 g of bicycloöctene (9.24 mmoles) was then added. The yellow color faded after the mixture stirred five minutes; 9.24 ml of 3.0 M sodium hydroxide were added, followed by 9.24 ml of 0.5 M sodium borohydride in 3.0 M sodium hydroxide. Upon addition of the sodium hydroxide, the yellow color returned, and upon addition of the sodium borohydride mixture, a dark gray-black color formed indicating the formation of mercury. The mercury was allowed to settle and the tetrahydrofuran and water layers were then decanted. Sodium chloride was added to saturation and the two layers separated in a separatory funnel. The tetrahydrofuran layer was then dried over magnesium sulfate, and filtered. The solvent evaporated leaving a crude crystalline solid. After one recrystallization from pentane a
melting point of $178.5^{\circ}-179.5^{\circ} \mathrm{C}$ was obtained for the alcohol, corresponding to a yield of 0.6067 g .

According to the procedure of Walborsky, Baum, and Youssef ${ }^{13}, 1.30 \mathrm{~g}$ of recrystallized p-bromobenzenesulfonylchloride was added to 0.60 g of bicyclo [2.2.2] octanol-2 dissolved in 3 ml of anhydrous pyridine while stirring and cooling in an acetone-water-ice bath. The reaction mixture was placed in a freezer for fifty minutes and then moved to the warmer compartment of the refrigerator for approximately 64.5 hours. The mixture was then poured over ice ( 10 ml ) and water ( 5 ml ) and stirred in a acetone-water-ice bath. When the ice had amost melted the mixture was filtered and the solid filtrate was placed in a dessicator to dry. This procedure yielded 0.3352 g of crude product with a melting point of $78^{\circ}-79.5^{\circ} \mathrm{C}$. The crude bicyclo [2.2.2] octyl-2 p-bromobenzenesulfonate was recrystallized from petroleum ether by slow growth from solvent evaporation over a period of six days. The pure crystals used in the final collection of $x$-ray data gave a melting point of $83^{\circ}-84^{\circ} \mathrm{C}$. Carbon, Hydrogen, Sulfur Analysis

A carbon, hydrogen, and sulfur analysis was conducted on the crystals by Atlantic Microlab, Inc., Atlanta, Georgia. The calculated weight per cents were $\% C=48.70$ per cent, $\% H=4.93$ per cent, and $\% S=9.28$ per cent. The experimental weight per cents were $\% C=48.66$ per cent, $\% H=4.94$ per cent,
and $\%$ S $=9.31$ per cent.

## Crystallographic Study

## Calculations

The calculations were carried out with the aid of several computer programs including modified versions of $F$. L. Carter's program for calculating diffractometer settings ${ }^{14}$; Zalkin's FORDAP Fourier summation program ${ }^{15}$; a direct rewrite of the Ibers/Doedens program RBANG ${ }^{16}$; $\operatorname{BECLS}(6)^{17}$, a locally modified version of the Ibers/Doedens program NUCLS5, which is a highly modified version of ORFLS18; Busing - Martin Levy's ORFFEl9; Johnson's ORTEP thermal ellipsoid plotting program ${ }^{20}$; and locally written programs for data reduction. The program RBANG defines a set of orthogonal axes from the crystal axes and provides the orientation angles phi, theta, and rho for a group of atoms to be refined as a rigid body to be used as input for BECLS (6). BECLS (6) allows refinement of individual atoms and/or rigid groups. Structure Elucidation of Bicyclo [2.2.2] octyl-2 p-bromobenzenesulfonate

The crystals grown in petroleum ether were cut to adequate size for the space group determination and the data collection. The space group was determined using a crystal mounted on a glass rod attached to the goniometer head so that the $\mathrm{b}^{*}$ axis was coincident with the spindle axis of the precession camera. The space group indicated by the precession photographs, $\mathrm{P} 2 \mathrm{l} / \mathrm{C}$, No. $14^{21}$, ( $0 \mathrm{k} 0, \mathrm{k}=2 \mathrm{n}$; h01, $1=2 \mathrm{n}$ ),
was later found to be in error because the hol reflections where $1 \neq 2 \mathrm{n}$ were weak and were not visible on the photographs. The space group was later found to be $\mathrm{P} 2_{1}$, No. $4^{21}$, ( $0 \mathrm{k} 0, \mathrm{k}=2 \mathrm{n}$ ), from diffractometer data. It was discovered that the crystal reacted both with the ethyl acetate in certain glues and with the water vapor in the air at room temperature. Therefore, the crystal was mounted in a sealed glass capillary of approximately 0.5 mm diameter. This capillary was then mounted on the goniometer head. Under these conditions the crystal still decomposed slowly at room temperature in the x-ray beam. Three sets of data were collected or partially collected because of mounting problems and instrument malfunction. The final set, Data III, was used for the solution of the structure. The nearly cubical crystal used in collecting Data III had been cut from a larger crystal and had dimensions of $0.45 \times 0.50 \times 0.35 \mathrm{~mm}$. The b* axis was coincident with the $\phi$-axis of the diffractometer. After approximate alignment on the precession camera the crystal was realigned on the Picker four-circle diffractometer according to published instructions ${ }^{22}$. The four angles ( $\phi$, $\times, \omega$ and $2 \theta$ ) which define the position of the crystal and detector so that the intensity of a reflection can be measured were determined for 10 reflections and the angle settings for the data collection were calculated. The limits set on the Carter program were H from -10 to 10 , K from zero to 12 , L from zero to 12 . However, all peaks of significant
intensity were found to be within a range of $\theta$ from zero to $25^{\circ}$, or diffractometer angle $2 \theta$ from $180^{\circ}$ to $230^{\circ}$. The cell parameters calculated by least squares treatment of the defining angles of 22 reflections, using the crystal aligned first (Data I), were $a=10.150(3) \stackrel{\circ}{\mathrm{A}}, \mathrm{b}=12.415(3) \stackrel{\circ}{\mathrm{A}}, \mathrm{c}=13.060(4)$ $\AA, \alpha=90.00^{\circ}, \beta=117.11(1)^{\circ}, \gamma=90.00^{\circ}$, and the cell volume $=1465.06 \AA^{3}$ at $25^{\circ} \mathrm{C}$ using molybdenum $\mathrm{K} \alpha$ radiation $(\lambda=$ $0.7107 \mathrm{~A})$. The density calculated from the cell volume assuming four molecules per unit cell, $1.56 \mathrm{~g} / \mathrm{cm}^{3}$, agreed well with the density calculated by the flotation method, 1.54 $\mathrm{g} / \mathrm{cm}^{3}$.

The intensities were measured with a scintillation counter mounted 26 cm from the crystal, and they were collected by the $\theta-2 \theta$ scan technique at a scan rate of $1^{\circ}$ per minute. A symmetrical $2^{\circ}$ scan was taken about the calculated $2 \theta$ angle for each reflection, and stationary background counts of 20 seconds were taken at the beginning (BI) and the end (B2) of the $2^{\circ}$ scan. The scan of each reflection was monitored by a strip recorder, and in some cases $K \beta$ peaks were observed. When it was possible to exclude the $K \beta$ peak, 0.5 degree was removed from the scan and the background counts were reduced to 15 seconds each. Calibrated copper attenuators were used in the data collection and the threshold point was set so that the counting rate would not exceed $10^{4}$ counts per second. The pulse height analyzer was set for approximately a 90 per cent window, centered on the
molybdenum $\mathrm{K} \alpha$ peak. Two standard reflections (3 30 and 0 $110)$ were scanned approximately every 35 reflections. Reflection 330 was used to monitor the alignment and the decomposition of the crystal, and 0110 (a systematically absent reflection) was used to check for false intensity caused by electrical noise; these reflections, which were repeated during the data collection, were averaged. The intensity of the standard reflection, 330 , decreased significantly during the data collection period due to decomposition. The data set was corrected for this loss of intensity by multiplying the intensity of each reflection (corrected for background) by a correction factor, which was equal to the intensity (corrected for background) of the initial standard reflection ( 3 3 0 ) divided by the intensity (corrected for background) of the standard ( $\left.\begin{array}{lll}3 & 3 & 0\end{array}\right)$ immediately preceding. The correction for background was made according to the following formula:

$$
I=C T-0.5\left(t_{c} / t_{b}\right)(B 1+B 2)
$$

where $I$ is the corrected intensity, CT is the total integrated peak count, $t_{c}$ is the scan time, and $t_{b}$ is the counting time of each background (either B1 or B2). A standard deviation for each reflection was calculated according to the formula

$$
\sigma(\mathrm{I})=\left[\mathrm{CT}+0.25\left(\mathrm{t}_{\mathrm{c}} / \mathrm{t}_{\mathrm{b}}\right)^{2}(\mathrm{~B} 1+\mathrm{B} 2)+(\mathrm{pI})^{2}\right]^{1 / 2}
$$

where $\sigma(I)$ is the standard deviation and $p$, which accounts for unknown random errors, equals 0.02. Initially, 771 reflections were accepted on the basis that the intensity (I) was greater than three times the standard deviation. Later, four reflections were rejected because of irregular, or very high backgrounds. The intensities were corrected for lorentz and polarization effects, but not for absorption effects. The linear absorption coefficient, $\mu$, was calculated to be $31 \mathrm{~cm}^{-1}$ according to the formula

$$
\mu=\frac{n}{V} \sum_{i}^{N}\left[1\left[\left(\mu_{a}\right) A\right]_{i}\right.
$$

where n is the number of molecules per unit cell, $V$ is the volume of the unit cell, $N$ is the number of different types of atoms in the molecule, $\mu_{a}$ is the atomic absorption coefficient, and $A$ is the number of atoms of type a.

The two independent bromine atoms and the two independent sulfur atoms were located from a three dimensional Patterson synthesis using Data I. The reflections collected in Data I were found to have incorrect intensities due to an instrument malfunction which caused electrical noise to
be recorded as intensity. The remaining structure was derived from suceeding electron density maps based on Data III. The carbon atoms in the two phenyl rings were located and refined as rigid groups; the oxygen atoms were located and their coordinates refined. Atoms in the vicinity of the bicycloöctanes were found and were refined as rigid groups. The structure was refined with weights equal to one resulting in a conventional $R_{1}$ value $\left(R_{1}=\Sigma| | F_{0}\left|-\left|F_{C}\right|\right| / \Sigma\left|F_{0}\right|\right)$ of 0.200. A weighting scheme based on counting statistics $(w=$ $\left.4 I /[\sigma(I)]^{2}\right)$ was introduced and $R_{1}$ and $R_{2}\left(R_{2}=\left[\sum W\left(\left|F_{0}\right|-\right.\right.\right.$ $\left.\left.\left|F_{c}\right|\right)^{2} / \Sigma \mathrm{w}\left(\left|F_{o}\right|\right)^{2}\right]^{1 / 2}$, reached values of 0.116 and 0.122 respectively. Each bicycloöctane group was then refined as two groups, each consisting of a bridgehead carbon and the three bonded carbons; $R_{1}$ and $R_{2}$ then equaled 0.111 and 0.112 respectively. The bicycloöctane atoms were then allowed to refine individually and bond distances were calculated. When the bond distances were found to be unsatisfactory disorder was suspected. Peaks were found in the electron density map in the vicinity of one of the bicycloöctane groups (BIC2) and one in the vicinity of the oxygens of the same molecule. The structure was refined, assuming disorder, with fractional atoms at the positions observed, and although the $R$ values were lower $\left(\mathrm{R}_{1}=0.096, \mathrm{R}_{2}=0.090\right)$, the bond distances did not improve and no alternate (disordered) group could be clearly seen. Different sets of eight carbon atoms were
chosen for BIC2 and they refined to essentially the same positions. The structure was then refined with the normal number of carbon atom positions in the bicycloöctane groups and one of the three oxygen positions in BIC2 split between two positions. The refinement of scale factor, the coordinates of each atom, and the individual isotropic temperature factors (122 variable parameters) was continued until no parameter varied more than 22.2 per cent of the estimated standard deviation; $R_{1}$ and $R_{2}$ converged to values of 0.0984 and 0.0929 respectively (Run 21A). When the structure had been refined with only one position for each atom (118 variable parameters), $R_{1}$ and $R_{2}$ converged to values of 0.1016 and 0.0975 respectively, and no parameter varied more than 67.6 per cent of the estimated standard deviation (Run 24A). The scattering factors tabulated by Ibers ${ }^{21}$ were employed for all atoms in the structure factor calculations.

## CHAPTER IV

RESULTS
The observed and calculated structure factors for the 767 nonzero, unique reflections are given in Table 1. The positional and isotropic thermal parameters with their standard deviations in parentheses are listed in Table 2. These values are taken from the last cycle of leastsquares refinement with one position per atom (Run 24A). Group isotropic thermal parameters are listed for the phenyl groups. The standard deviations listed for the phenyl carbons are the group origin standard deviations.

## CHAPTER V

## DISCUSSION OF RESULTS

After initial positions for all atoms had been chosen and their parameters refined, the bond distances were calculated. The values varied as much as 0.5 A from accepted values. Because of the problem of phasing in an asymmetric space group, the reliability of the electron density maps was questioned. In order to choose the best atom positions, each of the two independent bicyclo [2.2.2] octane groups was then refined as a rigid body. Next, each bicycloöctane was refined as two groups, each consisting of a bridgehead and the three carbon atoms bonded to it. Finally, the atoms in the bicycloöctane groups were refined individually. The bond distances improved somewhat, but still varied as much as $0.25 \AA$ from accepted values in $B I C l$ and as much as $0.45 \AA$ in BIC2 (Run 24A). $R_{1}$ and $R_{2}$ converged to values of 0.1016 and 0.0975 respectively. At this point disorder was suspected and fractional atoms were introduced in one of the bicycloöctane groups (BIC2) in the hope of finding definite enantiomeric disorder. Such disorder was found in the crystal structure of a similar compound, racemic 2-exo-norbornanol ptoluenesulfonate, by Altona and Sundaralingam ${ }^{23}$. The disorder in that structure caused by approximately a 3:1 ratio
of the two enantiomeres occupying the same area in the unit cell. The same type of disorder was possible with the two enantiomeres of bicyclo [2.2.2] octyl-2 p-bromobenzenesulfonate. After several cycles of refinement one of the fractional positions developed an unusually low temperature factor indicating more electron density than usual for a carbon atom. Since this position was in the vicinity of the BIC2 oxygen atoms, it was refined as a fractional oxygen position. Refining the atoms in this manner gave the lowest $R_{1}$ and $R_{2}$ values attained, 0.096 and 0.090 respectively. However, the bond distances were worse and no alternate group of atoms gave a better set of bicycloöctane bond distances. The structure was then refined with the normal number of carbon atom positions, the only fractional positions being two positions for one BIC2 oxygen atom. The bond distances then varied as much as $0.65 \stackrel{\circ}{\mathrm{~A}}$ from accepted values, and $\mathrm{R}_{1}$ and $\mathrm{R}_{2}$ refined to 0.0984 and 0.0929 respectively (Run 21 A ).

The bicycloöctane sulfur-oxygen bond distances, the oxygen-carbon bond distances and the carbon-carbon bond distances derived from Runs 2lA and 24 A for BICl and BIC2 are compared in Table 3 with standard deviations in parentheses. In both runs the bond distances in BICl were usually closer to accepted values than the bond distances in BIC2. In Run 24A the sulfur-oxygen bond distances in BICl are quite reasonable, Sl-S101 being slightly longer than Sl-S102 and Sl-S103

because Sl01 is bonded to BlC2 (see Figure 1). In Run 21A the Sl-Sl02 and Sl-Sl03 distances are also reasonable but the Sl-Sl01 bond distance (1.052(4) $\AA$ ) is much too short. The Slol-BlC2 bond distance is also better in Run 24A (1.537(11) A) than in Run 21A (1.639(2) A). A comparison of the other bond distances in Run 24A to those in Run 21A indicates that the number of bond distances which improve approximately equals the number of bond distances which become worse; however, the extremes are not as great in Run 24A. The agreement between the observed and the calculated structure factors in Run 21A $\left(R_{1}=0.0984\right.$ and $\left.R_{2}=0.0929\right)$ is better than the agreement in Run $24 \mathrm{~A}\left(\mathrm{R}_{1}=0.1016\right.$ and $R_{2}=0.0975$ ). The difference in refinement between 21A and 24A has better than a 99.5 per cent probability of being significant (21A supposedly being the better model) according to the Hamilton $R$-factor test ${ }^{25}$ which takes into account the increased number of variables in Run 2lA. However, the fact that the bond distances are less reasonable in Run 21A probably indicates problems in the data set due to decomposition and/or instrumental problems. Also, a small absorption error could have been introduced due to irregularities in the glass capillary or to the $x$-ray beam passing through varying thickness of glass because of changing orientation of the detector with respect to the capillary. Another possible explanation is inconsistent crystal disorder which cannot be accounted
for in the least squares refinement.
The bicycloöctane group in the molecule with the most reasonable bond distances was determined to be BICl using the positions taken from Run 24A. This bicycloöctane group was the closest to $D_{3}$ symmetry. The dihedral angles between the BlCl-BlC2-BlC4 and the BlCl-BlC3-BlC4 planes (P), between the BlCl-BlC6-BlC4 and the BlCl-BlC5-BlC4 planes (Q), and between the BlCl-BlC7-BlC4 and the BlCl-BlC8-BlC4 planes (R) were calculated; $P=10.4(1)^{\circ}, Q=8.3(0)^{\circ}$, and $R=17.8(2)^{\circ}$ with a standard deviation equal to $5.0^{\circ}$. These angles indicate twisting about the bridgehead-bridgehead axis; however, it must be remembered that these angles are very sensitive to variation in atom positions. Also, the calculations from other runs showed the group deviating from $D_{3}$ symmetry to the extent that different bridges appeared twisted in different directions.

The bond angles for BICl and BIC2 from Run 24A are listed in Table 4.

Table 4. Bond Angles for Bicyclo [2.2.2] octyl-2 p-bromobenzenesulfonate From Run 24A

| Atoms | Angle, degrees | Atoms | Angle, degrees |

## CHAPTER VI

## RECOMMENDATIONS

Almost every bicyclo [2.2.2] octane compound whose crystal structure has been studied using x-ray diffraction has belonged to the centric space group $\mathrm{P} 2_{1} / \mathrm{C}$. The only exception found, omitting this study, was the study of compound III $^{24}$.

III

It seems likely, therefore, that if other bridge-substituted bicyclo [2.2.2] octanes were chosen, one could be found which crystallized in a centric space group. If this compound were found free of disorder, then atoms could be chosen more accurately from a more reliable electron density map.

Solvents other than petroleum ether or different crystallization conditions could be used in the crystallization of bicyclo [2.2.2] octyl-2 p-bromobenzenesulfonate. In either case crystals might be produced free from the problems of disorder.
